Preface

Each of the first two editions of *The Prokaryotes* took a bold step. The first edition, published in 1981, set out to be an encyclopedic, synoptic account of the world of the prokaryotes—a collection of monographic descriptions of the genera of bacteria. The Archaea had not yet been formalized as a group. For the second edition in 1992, the editors made the decision to organize the chapters on the basis of the molecular phylogeny championed by Carl Woese, which increasingly provided a rational, evolutionary basis for the taxonomy of the prokaryotes. In addition, the archaea had by then been recognized as a phylogenetically separate and distinguishable group of the prokaryotes. The two volumes of the first edition had by then expanded to four. The third edition was arguably the boldest step of all. We decided that the material would only be presented electronically. The advantages were obvious and persuasive. There would be essentially unlimited space. There would be no restrictions on the use of color illustrations. Film and animated descriptions could be made available. The text would be hyperlinked to external sources. Publication of chapters would be seriatim—the edition would no longer have to delay publication until the last tardy author had submitted his or her chapter. Updates and modifications could be made continuously. And, most attractively, a library could place its subscribed copy on its server and make it available easily and cheaply to all in its community. One hundred and seventy chapters have thus far been presented in 16 releases over a six-year period. The virtues and advantages of the online edition have been borne out. But we failed to predict the affection that many have for holding a bound, print version of a book in their hands. Thus, this print version of the third edition shall accompany the online version.

We are now four years into the 21st century. Indulge us then while we comment on the challenges, problems and opportunities for microbiology that confront us.

Moselio Schaechter has referred to the present era of microbiology as its third golden age—the era of “integrative microbiology.” Essentially all microbiologists now speak a common language. So that the boundaries that previously separated subdisciplines from each other have faded: physiology has become indistinguishable from pathogenesis; ecologists and molecular geneticists speak to each other; biochemistry is spoken by all; and—mirabile dictu!—molecular biologists are collaborating with taxonomists.

But before these molecular dissections of complex processes can be effective there must be a clear view of the organism being studied. And it is our goal that these chapters in *The Prokaryotes* provide that opportunity.

There is also yet a larger issue. Microbiology is now confronted with the need to understand increasingly complex processes. And the modus operandi that has served us so successfully for 150 years—that of the pure culture studied under standard laboratory conditions—is inadequate. We are now challenged to solve problems of multimembered populations interacting with each other and with their environment under constantly variable conditions. Carl Woese has pointed out a useful and important distinction between empirical, methodological reductionism and fundamentalist reductionism. The former has served us well; the latter stands in the way of our further understanding of complex, interacting systems. But no matter what kind of synoptic systems analysis emerges as our way of understanding host–parasite relations, ecology, or multicellular behavior, the understanding of the organism as such is *sine qua non*. And in that context, we are pleased to present to you the third edition of *The Prokaryotes*.

Martin Dworkin
Editor-in-Chief

Foreword

The purpose of this brief foreword is unchanged from the first edition; it is simply to make you, the reader, hungry for the scientific feast that follows. These four volumes on the prokaryotes offer an expanded scientific menu that displays the biochemical depth and remarkable physiological and morphological diversity of prokaryote life. The size of the volumes might initially discourage the unprepared mind from being attracted to the study of prokaryote life, for this landmark assemblage thoroughly documents the wealth of present knowledge. But in confronting the reader with the state of the art, the Handbook also defines where more work needs to be done on well-studied bacteria as well as on unusual or poorly studied organisms.

This edition of *The Prokaryotes* recognizes the almost unbelievable impact that the work of Carl Woese has had in defining a phylogenetic basis for the microbial world. The concept that the ribosome is a highly conserved structure in all cells and that its nucleic acid components may serve as a convenient reference point for relating all living things is now generally accepted. At last, the phylogeny of prokaryotes has a scientific basis, and this is the first serious attempt to present a comprehensive treatise on prokaryotes along recently defined phylogenetic lines. Although evidence is incomplete for many microbial groups, these volumes make a statement that clearly illuminates the path to follow.

There are basically two ways of doing research with microbes. A classical approach is first to define the phenomenon to be studied and then to select the organism accordingly. Another way is to choose a specific organism and go where it leads. The pursuit of an unusual microbe brings out the latent hunter in all of us. The intellectual challenges of the chase frequently test our ingenuity to the limit. Sometimes the quarry repeatedly escapes, but the final capture is indeed a wonderful experience. For many of us, these simple rewards are sufficiently gratifying so that we have chosen to spend our scientific lives studying these unusual creatures. In these endeavors many of the strategies and tools as

well as much of the philosophy may be traced to the Delft School, passed on to us by our teachers, Martinus Beijerinck, A. J. Kluyver, and C. B. van Niel, and in turn passed on by us to our students.

In this school, the principles of the selective, enrichment culture technique have been developed and diversified; they have been a major force in designing and applying new principles for the capture and isolation of microbes from nature. For me, the “organism approach” has provided rewarding adventures. The organism continually challenges and literally drags the investigator into new areas where unfamiliar tools may be needed. I believe that organism-oriented research is an important alternative to problem-oriented research, for new concepts of the future very likely lie in a study of the breadth of microbial life. The physiology, biochemistry, and ecology of the microbe remain the most powerful attractions. Studies based on classical methods as well as modern genetic techniques will result in new insights and concepts.

To some readers, this edition of the *The Prokaryotes* may indicate that the field is now mature, that from here on it is a matter of filling in details. I suspect that this is not the case. Perhaps we have assumed prematurely that we fully understand microbial life. Van Niel pointed out to his students that—after a lifetime of study—it was a very humbling experience to view in the microscope a sample of microbes from nature and recognize only a few. Recent evidence suggests that microbes have been evolving for nearly 4 billion years. Most certainly those microbes now domesticated and kept in captivity in culture collections represent only a minor portion of the species that have evolved in this time span. Sometimes we must remind ourselves that evolution is actively taking place at the present moment. That the eukaryote cell evolved as a chimera of certain prokaryote parts is a generally accepted concept today. Higher as well as lower eukaryotes evolved in contact with prokaryotes, and evidence surrounds us of the complex interactions between eukaryotes and

prokaryotes as well as among prokaryotes. We have so far only scratched the surface of these biochemical interrelationships. Perhaps the legume nodule is a pertinent example of nature caught in the act of evolving the “nitrosome,” a unique nitrogen-fixing organelle. Study of prokaryotes is proceeding at such a fast pace that major advances are occurring yearly. The increase of this edition to four volumes documents the exciting pace of discoveries.

To prepare a treatise such as *The Prokaryotes* requires dedicated editors and authors; the task has been enormous. I predict that the scientific community of microbiologists will again show its appreciation through use of these volumes—such that the pages will become “dog-eared” and worn as students seek basic information for the

hunt. These volumes belong in the laboratory, not in the library. I believe that a most effective way to introduce students to microbiology is for them to isolate microbes from nature, i.e., from their habitats in soil, water, clinical specimens, or plants. *The Prokaryotes* enormously simplifies this process and should encourage the construction of courses that contain a wide spectrum of diverse topics. For the student as well as the advanced investigator these volumes should generate excitement.

Happy hunting!

Volume 5**3. *Proteobacteria***

	Introduction to the Proteobacteria KAREL KERSTERS, PAUL DE VOS, MONIQUE GILLIS, JEAN SWINGS, PETER VAN DAMME and ERKO STACKEBRANDT	3
 3.1.	 <i>Alpha Subclass</i>	
3.1.1	The Phototrophic Alpha-Proteobacteria JOHANNES F. IMHOFF	41

3.1.2	The Genera <i>Prosthecomicrobium</i> and <i>Ancalomicrobium</i> GARY E. OERTLI, CHERYL JENKINS, NAOMI WARD, FREDERICK A. RAINEY, ERKO STACHEBRANDT and JAMES T. STALEY	65
3.1.3	Dimorphic Prosthecate Bacteria: The Genera <i>Caulobacter</i> , <i>Asticcacaulis</i> , <i>Hyphomicrobium</i> , <i>Pedomicrobium</i> , <i>Hyphomonas</i> and <i>Thiodendron</i> JEANNE S. POINDEXTER	72
3.1.4	The Genus <i>Agrobacterium</i> ANN G. MATTHYSSE	91
3.1.5	The Genus <i>Azospirillum</i> ANTON HARTMANN and JOSE IVO BALDANI	115
3.1.6	The Genus <i>Herbaspirillum</i> MICHAEL SCHMID, JOSE IVO BALDANI and ANTON HARTMANN	141
3.1.7	The Genus <i>Beijerinckia</i> JAN HENDRICK BECKING	151
3.1.8	The Family Acetobacteraceae: The Genera <i>Acetobacter</i> , <i>Acidomonas</i> , <i>Asaia</i> , <i>Gluconacetobacter</i> , <i>Gluconobacter</i> , and <i>Kozakia</i> KAREL KERSTERS, PUSPITA LISDIYANTI, KAZUO KOMAGATA and JEAN SWINGS	163
3.1.9	The Genus <i>Zymomonas</i> HERMANN SAHM, STEPHANIE BRINGER-MEYER and GEORG A. SPRENGER	201
3.1.10	The Manganese-Oxidizing Bacteria KENNETH H. NEALSON	222
3.1.11	The Genus <i>Paracoccus</i> DONOVAN P. KELLY, FREDERICK A. RAINEY and ANN P. WOOD	232
3.1.12	The Genus <i>Phenylobacterium</i> JÜRGEN EBERSPÄCHER and FRANZ LINGENS	250
3.1.13	<i>Methylobacterium</i> PETER N. GREEN	257
3.1.14	The Methanotrophs—The Families Methylococcaceae and Methylocystaceae JOHN P. BOWMAN	266
3.1.15	The Genus <i>Xanthobacter</i> JÜRGEN WIEGEL	290
3.1.16	The Genus <i>Brucella</i> EDGARDO MORENO and IGNACIO MORIYÓN	315
3.1.17	Introduction to the Rickettsiales and Other Intracellular Prokaryotes DAVID N. FREDRICKS	457
3.1.18	The Genus <i>Bartonella</i> MICHAEL F. MINNICK and BURT E. ANDERSON	467

3.1.19	The Order Rickettsiales XUE-JIE YU and DAVID H. WALKER	493
3.1.20	The Genus <i>Coxiella</i> ROBERT A. HEINZEN and JAMES E. SAMUEL	529
3.1.21	The Genus <i>Wolbachia</i> MARKUS RIEGLER and SCOTT L. O'NEILL	547
3.1.22	Aerobic Phototrophic Proteobacteria VLADIMIR V. YURKOV	562
3.1.23	The Genus <i>Seliberia</i> JEAN M. SCHMIDT and JAMES R. SWAFFORD	585
3.2.	<i>Beta Subclass</i>	
3.2.1	The Phototrophic Betaproteobacteria JOHANNES F. IMHOFF	593
3.2.2	The <i>Neisseria</i> DANIEL C. STEIN	602
3.2.3	The Genus <i>Bordetella</i> ALISON WEISS	648
3.2.4	<i>Achromobacter</i> , <i>Alcaligenes</i> and Related Genera HANS-JÜRGEN BUSSE and ANDREAS STOLZ	675
3.2.5	The Genus <i>Spirillum</i> NOEL R. KRIEG	701
3.2.6	The Genus <i>Aquaspirillum</i> BRUNO POT, MONIQUE GILLIS and JOZEF DE LEY	710
3.2.7	<i>Comamonas</i> ANNE WILLEMS and PAUL DE VOS	723
3.2.8	The Genera <i>Chromobacterium</i> and <i>Janthinobacterium</i> MONIQUE GILLIS and JOZEF DE LEY	737
3.2.9	The Genera <i>Phyllobacterium</i> and <i>Ochrobactrum</i> JEAN SWINGS, BART LAMBERT, KAREL KERSTERS and BARRY HOLMES	747
3.2.10	The Genus <i>Derxia</i> JAN HENDRICK BECKING	751
3.2.11	The Genera <i>Leptothrix</i> and <i>Sphaerotilus</i> STEFAN SPRING	758
3.2.12	The Lithoautotrophic Ammonia-Oxidizing Bacteria HANS-PETER KOOPS, ULRIKE PURKHOLD, ANDREAS POMMERENING-RÖSER, GABRIELE TIMMERMANN and MICHAEL WAGNER	778

3.2.13	The Genus <i>Thiobacillus</i> LESLEY A. ROBERTSON and J. GIJS KUENEN	812
3.2.14	The Genera <i>Simonsiella</i> and <i>Alysiella</i> BRIAN P. HEDLUND and DAISY A. KUHN	828
3.2.15	<i>Eikenella corrodens</i> and Closely Related Bacteria EDWARD J. BOTTONE and PAUL A. GRANATO	840
3.2.16	The Genus <i>Burkholderia</i> DONALD E. WOODS and PAMELA A. SOKOL	848
3.2.17	The Nitrite-Oxidizing Bacteria AHARON ABELIOVICH	861
3.2.18	The Genera <i>Azoarcus</i> , <i>Azovibrio</i> , <i>Azospira</i> and <i>Azonexus</i> BARBARA REINHOLD-HUREK and THOMAS HUREK	873
Index		893

Volume 6

3. *Proteobacteria*

3.3. *Gamma Subclass*

3.3.1	New Members of the Family Enterobacteriaceae J. MICHAEL JANDA	5
3.3.2	Phylogenetic Relationships of Bacteria with Special Reference to Endosymbionts and Enteric Species M. PILAR FRANCINO, SCOTT R. SANTOS and HOWARD OCHMAN	41
3.3.3	The Genus <i>Escherichia</i> RODNEY A. WELCH	60
3.3.4	The Genus <i>Edwardsiella</i> SHARON L. ABBOTT and J. MICHAEL JANDA	72
3.3.5	The Genus <i>Citrobacter</i> DIANA BORENSHTEIN and DAVID B. SCHAUER	90
3.3.6	The Genus <i>Shigella</i> YVES GERMANI and PHILIPPE J. SANSONETTI	99
3.3.7	The Genus <i>Salmonella</i> CRAIG D. ELLERMEIER and JAMES M. SLAUCH	123
3.3.8	The Genus <i>Klebsiella</i> SYLVAIN BRISSE, FRANCINE GRIMONT and PATRICK A. D. GRIMONT	159

3.3.9	The Genus <i>Enterobacter</i> FRANCINE GRIMONT and PATRICK A. D. GRIMONT	197
3.3.10	The Genus <i>Hafnia</i> MEGAN E. MCBEE and DAVID B. SCHAUER	215
3.3.11	The Genus <i>Serratia</i> FRANCINE GRIMONT and PATRICK A. D. GRIMONT	219
3.3.12	The Genera <i>Proteus</i> , <i>Providencia</i> , and <i>Morganella</i> JIM MANOS and ROBERT BELAS	245
3.3.13	<i>Y. enterocolitica</i> and <i>Y. pseudotuberculosis</i> ELISABETH CARNIEL, INGO AUTENRIETH, GUY CORNELIS, HIROSHI FUKUSHIMA, FRANÇOISE GUINET, RALPH ISBERG, JEANNETTE PHAM, MICHAEL PRENTICE, MICHEL SIMONET, MIKAEL SKURNIK and GEORGES WAUTERS	270
3.3.14	<i>Yersinia pestis</i> and Bubonic Plague ROBERT BRUBAKER	399
3.3.15	<i>Erwinia</i> and Related Genera CLARENCE I. KADO	443
3.3.16	The Genera <i>Photorhabdus</i> and <i>Xenorhabdus</i> NOEL BOEMARE and RAYMOND AKHURST	451
3.3.17	The Family Vibrionaceae J. J. FARMER, III	495
3.3.18	The Genera <i>Vibrio</i> and <i>Photobacterium</i> J. J. FARMER, III and F. W. HICKMAN-BRENNER	508
3.3.19	The Genera <i>Aeromonas</i> and <i>Plesiomonas</i> J. J. FARMER, III, M. J. ARDUINO and F. W. HICKMAN-BRENNER	564
3.3.20	The Genus <i>Alteromonas</i> and Related Proteobacteria VALERY V. MIKHAILOV, LYUDMILA A. ROMANENKO and ELENA P. IVANOVA	597
3.3.21	Nonmedical: <i>Pseudomonas</i> EDWARD R. B. MOORE, BRIAN J. TINDALL, VITOR A. P. MARTINS DOS SANTOS, DIETMAR H. PIEPER, JUAN-LUIS RAMOS and NORBERTO J. PALLERONI	646
3.3.22	<i>Pseudomonas aeruginosa</i> TIMOTHY L. YAHR and MATTHEW R. PARSEK	704
3.3.23	Phytopathogenic Pseudomonads and Related Plant-Associated Pseudomonads MILTON N. SCHROTH, DONALD C. HILDEBRAND and NICKOLAS PANOPOULOS	714
3.3.24	<i>Xylophilus</i> ANNE WILLEMS and MONIQUE GILLIS	741

3.3.25	The Genus <i>Acinetobacter</i> KEVIN TOWNER	746
3.3.26	The Family Azotobacteraceae JAN HENDRICK BECKING	759
3.3.27	The Genera <i>Beggiatoa</i> and <i>Thioploca</i> ANDREAS TESKE and DOUGLAS C. NELSON	784
3.3.28	The Family Halomonadaceae DAVID R. ARAHAL and ANTONIO VENTOSA	811
3.3.29	The Genus <i>Deleya</i> KAREL KERSTERS	836
3.3.30	The Genus <i>Frateuria</i> JEAN SWINGS	844
3.3.31	The Chromatiaceae JOHANNES F. IMHOFF	846
3.3.32	The Family Ectothiorhodospiraceae JOHANNES F. IMHOFF	874
3.3.33	<i>Oceanospirillum</i> and Related Genera JOSÉ M. GONZÁLEZ and WILLIAM B. WHITMAN	887
3.3.34	<i>Serpens flexibilis</i> : An Unusually Flexible Bacterium ROBERT B. HESPELL	916
3.3.35	The Genus <i>Psychrobacter</i> JOHN P. BOWMAN	920
3.3.36	The Genus <i>Leucothrix</i> THOMAS D. BROCK	931
3.3.37	The Genus <i>Lysobacter</i> HANS REICHENBACH	939
3.3.38	The Genus <i>Moraxella</i> JOHN P. HAYS	958
3.3.39	<i>Legionella</i> Species and Legionnaire's Disease PAUL H. EDELSTEIN and NICHOLAS P. CIANCOTTO	988
3.3.40	The Genus <i>Haemophilus</i> DORAN L. FINK and JOSEPH W. ST. GEME, III	1034
3.3.41	The Genus <i>Pasteurella</i> HENRIK CHRISTENSEN and MAGNE BISGAARD	1062
3.3.42	The Genus <i>Cardiobacterium</i> SYDNEY M. HARVEY and JAMES R. GREENWOOD	1091

3.3.43	The Genus <i>Actinobacillus</i> JANET I. MACINNES and EDWARD T. LALLY	1094
3.3.44	The Genus <i>Francisella</i> FRANCIS NANO and KAREN ELKINS	1119
3.3.45	Ecophysiology of the Genus <i>Shewanella</i> KENNETH H. NEALSON and JAMES SCOTT	1133
3.3.46	The Genus <i>Nevskia</i> HERIBERT CYPIONKA, HANS-DIETRICH BABENZIEN, FRANK OLIVER GLÖCKNER and RUDOLF AMANN	1152
3.3.47	The Genus <i>Thiomargarita</i> HEIDE N. SCHULZ	1156
Index		1165

Volume 7

3. *Proteobacteria*

3.4 *Delta Subclass*

3.4.1	The Genus <i>Pelobacter</i> BERNHARD SCHINK	5
3.4.2	The Genus <i>Bdellovibrio</i> EDOUARD JURKEVITCH	12
3.4.3	The Myxobacteria LAWRENCE J. SHIMKETS, MARTIN DWORKIN and HANS REICHENBACH	31

3.5. *Epsilon Subclass*

3.5.1	The Genus <i>Campylobacter</i> TRUDY M. WASSENAAR and DIANE G. NEWELL	119
3.5.2	The Genus <i>Helicobacter</i> JAY V. SOLNICK, JANI L. O'ROURKE, PETER VAN DAMME and ADRIAN LEE	139
3.5.3	The Genus <i>Wolinella</i> JÖRG SIMON, ROLAND GROSS, OLIVER KLIMMEK and ACHIM KRÖGER	178

4. *Spirochetes*

4.1	Free-Living Saccharolytic Spirochetes: The Genus <i>Spirochaeta</i> SUSAN LESCHINE, BRUCE J. PASTER and ERCOLE CANALE-PAROLA	195
------------	---	-----

4.2	The Genus <i>Treponema</i> STEVEN J. NORRIS, BRUCE J. PASTER, ANNETTE MOTER and ULF B. GÖBEL	211
4.3	The Genus <i>Borrelia</i> MELISSA J. CAIMANO	235
4.4	The Genus <i>Leptospira</i> BEN ADLER and SOLLY FAINE	294
4.5	Termite Gut Spirochetes JOHN A. BREZNAK and JARED R. LEADBETTER	318
4.6	The Genus <i>Brachyspira</i> THADDEUS B. STANTON	330
5.	<i>Chlorobiaceae</i>	
5.1	The Family Chlorobiaceae JÖRG OVERMANN	359
6.	<i>Bacteroides and Cytophaga Group</i>	
6.1	The Medically Important <i>Bacteroides</i> spp. in Health and Disease C. JEFFREY SMITH, EDSON R. ROCHA and BRUCE J. PASTER	381
6.2	The Genus <i>Porphyromonas</i> FRANK C. GIBSON and CAROLINE ATTARDO GENCO	428
6.3	An Introduction to the Family Flavobacteriaceae JEAN-FRANÇOIS BERNARDET and YASUYOSHI NAKAGAWA	455
6.4	The Genus <i>Flavobacterium</i> JEAN-FRANÇOIS BERNARDET and JOHN P. BOWMAN	481
6.5	The Genera <i>Bergeyella</i> and <i>Weeksella</i> CELIA J. HUGO, BRITA BRUUN and PIET J. JOOSTE	532
6.6	The Genera <i>Flavobacterium</i> , <i>Sphingobacterium</i> and <i>Weeksella</i> BARRY HOLMES	539
6.7	The Order Cytophagales HANS REICHENBACH	549
6.8	The Genus <i>Saprospira</i> HANS REICHENBACH	591
6.9	The Genus <i>Haliscomenobacter</i> EPPE GERKE MULDER and MARIA H. DEINEMA	602
6.10	<i>Sphingomonas</i> and Related Genera DAVID L. BALKWILL, J. K. FREDRICKSON and M. F. ROMINE	605

6.11	The Genera <i>Empedobacter</i> and <i>Myroides</i> CELIA J. HUGO, BRITA BRUUN and PIET J. JOOSTE	630
6.12	The Genera <i>Chryseobacterium</i> and <i>Elizabethkingia</i> JEAN-FRANÇOIS BERNARDET, CELIA J. HUGO and BRITA BRUUN	638
6.13	The Marine Clade of the Family Flavobacteriaceae: The Genera <i>Aequorivita</i> , <i>Arenibacter</i> , <i>Cellulophaga</i> , <i>Croceibacter</i> , <i>Formosa</i> , <i>Gelidibacter</i> , <i>Gillisia</i> , <i>Maribacter</i> , <i>Mesonina</i> , <i>Muricauda</i> , <i>Polaribacter</i> , <i>Psychroflexus</i> , <i>Psychroserpens</i> , <i>Robiginitalea</i> , <i>Salegentibacter</i> , <i>Tenacibaculum</i> , <i>Ulvibacter</i> , <i>Vitellibacter</i> and <i>Zobellia</i> JOHN P. BOWMAN	677
6.14	Capnophilic Bird Pathogens in the Family Flavobacteriaceae: <i>Riemerella</i> , <i>Ornithobacterium</i> and <i>Coenonia</i> PETER VAN DAMME, H. M. HAFEZ and K. H. HINZ	695
6.15	The Genus <i>Capnocytophaga</i> E. R. LEADBETTER	709
6.16	The Genera <i>Rhodothermus</i> , <i>Thermonema</i> , <i>Hymenobacter</i> and <i>Salinibacter</i> AHARON OREN	712
7.	<i>Chlamydia</i>	
7.1	The Genus <i>Chlamydia</i> —Medical MURAT V. KALAYOGLU and GERALD I. BYRNE	741
8.	<i>Planctomyces and Related Bacteria</i>	
8.1	The Order Planctomycetales, Including the Genera <i>Planctomyces</i> , <i>Pirellula</i> , <i>Gemmata</i> and <i>Isosphaera</i> and the Candidatus Genera <i>Brocadia</i> , <i>Kuenenia</i> and <i>Scalindua</i> NAOMI WARD, JAMES T. STALEY, JOHN A. FUERST, STEPHEN GIOVANNONI, HEINZ SCHLESNER and ERKO STACHEBRANDT	757
9.	<i>Thermus</i>	
9.1	The Genus <i>Thermus</i> and Relatives MILTON S. DA COSTA, FREDERICK A. RAINEY and M. FERNANDA NOBRE	797
10.	<i>Chloroflexaceae and Related Bacteria</i>	
10.1	The Family Chloroflexaceae SATOSHI HANADA and BEVERLY K. PIERSON	815
10.2	The Genus <i>Thermoleophilum</i> JEROME J. PERRY	843
10.3	The Genus <i>Thermomicrobium</i> JEROME J. PERRY	849

10.4	The Genus <i>Herpetosiphon</i> NATUSCHKA LEE and HANS REICHENBACH	854
11.	<i>Verrucomicrobium</i>	
11.1	The Phylum Verrucomicrobia: A Phylogenetically Heterogeneous Bacterial Group HEINZ SCHLESNER, CHERYL JENKINS and JAMES T. STALEY	881
12.	<i>Thermotogales</i>	
12.1	Thermotogales ROBERT HUBER and MICHAEL HANNIG	899
13.	<i>Aquificales</i>	
13.1	Aquificales ROBERT HUBER and WOLFGANG EDER	925
14.	<i>Phylogenetically Unaffiliated Bacteria</i>	
14.1	Morphologically Conspicuous Sulfur-Oxidizing Eubacteria JAN W. M. LA RIVIÈRE and KARIN SCHMIDT	941
14.2	The Genus <i>Propionigenium</i> BERNHARD SCHINK	955
14.3	The Genus <i>Zoogloea</i> PATRICK R. DUGAN, DAPHNE L. STONER and HARVEY M. PICKRUM	960
14.4	Large Symbiotic Spirochetes: <i>Clevelandina</i> , <i>Cristispira</i> , <i>Diplocalyx</i> , <i>Hollandina</i> and <i>Pillotina</i> LYNN MARGULIS and GREGORY HINKLE	971
14.5	<i>Streptobacillus moniliformis</i> JAMES R. GREENWOOD and SYDNEY M. HARVEY	983
14.6	The Genus <i>Toxothrix</i> PETER HIRSCH	986
14.7	The Genus <i>Gallionella</i> HANS H. HANERT	990
14.8	The Genera <i>Caulococcus</i> and <i>Kusnezovia</i> JEAN M. SCHMIDT and GEORGI A. ZAVARZIN	996
14.9	The Genus <i>Brachyarcus</i> PETER HIRSCH	998

14.10	The Genus <i>Pelosigma</i> PETER HIRSCH	1001
14.11	The Genus <i>Siderocapsa</i> (and Other Iron- and Maganese-Oxidizing Eubacteria) HANS H. HANERT	1005
14.12	The Genus <i>Fusobacterium</i> TOR HOFSTAD	1016
14.13	Prokaryotic Symbionts of Amoebae and Flagellates KWANG W. JEON	1028
Index		1039

New Members of the Family Enterobacteriaceae

J. MICHAEL JANDA

In the last edition of this chapter, Don Brenner (Brenner, 1991) wrote:

“They are, nonetheless, important for a variety of reasons. They have innate importance as members of the family, to be compared and contrasted with their relatives, in attempts to define the phenotypic, phylogenetic, and ecological boundaries of the family.”

No words better define the current edition of this chapter as the number of genera of Enterobacteriaceae has risen 60%, from 15 to 24 (excluding *Raoultella*). This current list of 24 genera does not even include such organisms as *Alterococcus agarolyticus* and *Saccharobacter fermentatus*, taxa that are not formally discussed in this chapter, although they possess some characteristics associated with the family Enterobacteriaceae (Yaping et al., 1990; Shieh and Jean, 1998).

The exponential increase in new genera within the family Enterobacteriaceae has been fueled by molecular biology, including polymerase chain reaction (PCR) technology and 16S (small subunit) rDNA sequencing. This list of genera will no doubt continue to increase. What has resulted from this molecular onslaught is the basic fundamental knowledge that the family Enterobacteriaceae plays a critical role not only in enteric disease of humans and animals, but also as phytopathogens, as insect pathogens, and in industrial processes. Members of the family Enterobacteriaceae can be broadly classified into four main categories for convenience, although a number of these genera clearly overlap into multiple categories (Table 1). Probably the greatest explosion in our knowledge concerning enterobacteria stems from new insight into their role as endosymbionts of insects or of the parasites that feed on insect larvae (Moran and Baumann, 2000). Some genera, such as *Photorhabdus* and *Xenorhabdus*, may serve as new delivery vehicles of important bacterial toxins with insecticidal activity, replacing such classic agents as *Bacillus thuringiensis* (French-Constant and Bowen, 1999). Knowledge of the association that genera, such as *Brenneria* and *Pectobacterium*, have with plant diseases contin-

ues to expand as our understanding of their correct taxonomic position becomes apparent. Phylogenetic analysis has also revealed that some agents, such as *Calymmatobacterium granulomatis*, the causative agent of the sexually transmitted disease, donovanosis (granuloma inguinale), are actually members of the Enterobacteriaceae. Thus, our knowledge regarding the Enterobacteriaceae and factors regulating molecular evolution of endosymbionts, disease associations in humans, animals, and plants, biological applications, and ecologic niches will continue to expand at a rapid rate for the foreseeable future.

Arsenophonus (*Androcidium*)

In 1986, Werren et al. isolated the causative agent (*Arsenophonus nasoniae*) of the son-killer (*sk*) trait from infected tissues of the parasitic wasp, *Nasonia vitropenns*. The *sk* trait, a sex-ratio distorter, is carried by approximately 5% of female wasps from natural populations (Gherna et al., 1991). Infected wasps transmit the bacterium to fly pupae (wasp host) during oviposition and offspring then become infected perorally (Werren et al., 1986). The bacterium causes the death of only male wasp eggs (unfertilized) by arresting their maturation. Werren et al. (1986) recovered the slow-growing bacterium from tryptic soy and brain heart infusion broth cultures containing either infected *sk*-wasp tissues or hemolymph of fly pupae parasitized by *sk* females. *Arsenophonus nasoniae* was subsequently proven to be the causative agent of the *sk* trait by fulfilling Koch's postulates.

Arsenophonus nasoniae DNA was 0–5% related to DNA from 54 representative species of Enterobacteriaceae (Brenner, 1991). However, total DNA from strain *A. nasoniae* SK14 hybridized to an rRNA *Escherichia coli* sequence enriched for, but not exclusive to, members of the family Enterobacteriaceae (Gherna et al., 1991). SK14 was 62% related at 60°C and 42% related at 70°C to the *Escherichia coli* probe. These values are similar to those

Table 1. New members of the family Enterobacteriaceae: major associations.

Human pathogens	Phytopathogens	Insect pathogens, symbionts, and endosymbionts	Environmental, industrial, and animals
<i>Calymmatobacterium</i>	<i>Brenneria</i>	<i>Arsenophonus</i>	<i>Budvicia</i>
<i>Cedecea</i>	<i>Pantoea</i> ^b	<i>Buchnera</i>	<i>Buttiauxella</i>
<i>Ewingella</i>	<i>Pectobacterium</i>	<i>Photorhabdus</i>	<i>Obseumbacterium</i>
<i>Kluysvera</i>		<i>Sodalis</i>	<i>Pragia</i>
<i>Leclercia</i>		<i>Wigglesworthia</i>	<i>Trabulsiella</i> ^c
<i>Leminorella</i>		<i>Xenorhabdus</i>	
<i>Moellerella</i> ^a			
<i>Rahnella</i>			
<i>Tatumella</i>			
<i>Yokenella</i> ^a			

^aPrimarily isolated from humans, but not definitely shown to be a human pathogen.

^bAlso causes infrequent infections in humans (e.g., *P. agglomerans*).

^cPrimarily an environmental group, but occasionally recovered from clinical specimens.

exhibited by other members of the Enterobacteriaceae including *Providencia*, *Proteus mirabilis* and *Xenorhabdus nematophilus*. A phylogenetic tree based upon rRNA sequences of selected members of the family Enterobacteriaceae was constructed and indicates that the genus *Proteus* is the closest neighbor to strain SKI4 (Gherna et al., 1991). This relationship is further supported by the fact that the G+C content (39.5 mol%) and fatty acid composition (large amounts of C_{16:0} and 16:1 *cis* 9, smaller amounts of 14:0) of strain SKI4 are very similar to that of the genera *Proteus* and *Providencia*, respectively. A second putative species in the genus *Arsenophonus* has been detected as a “secondary (S)-endosymbiont” in the reduviid bug, *Triatoma infestans* (Hypša and Dale, 1997). A bacterial culture TI1 was isolated from the hemolymph of *T. infestans*. The TI1 bacteria could be propagated in vitro by cocultivation with a mosquito cell line (*Aedes albopictus*) but could not be cultured in vitro. PCR amplification of a 16S rDNA product (1361 bp) from TI1-*A. albopictus* cultures and comparison to other 16S rDNA sequences from eubacteria indicated that the endosymbiont was a member of the γ -3 subdivision of the class Proteobacteria (Hypša and Dale, 1997). The TI1 rDNA sequences are 96.2% related to those of *A. nasoniae* and a phylogenetic tree indicates that *A. nasoniae* is the most closely related taxa to TI1. Because TI1 cannot be cultured in vitro and valid biochemical tests cannot be performed, *Candidatus* status (provisional assignment) has been applied prior to the vernacular epithet (Murray and Schleifer, 1994; Hypša and Dale, 1997). Whether *Arsenophonus* contains the enterobacterial common antigen (ECA) is unknown.

Arsenophonus nasoniae is a fastidious Gram-negative, oxidase-negative, catalase-positive, non-sporeforming, nonmotile rod that produces

acid from D-glucose, fructose, and sucrose (Brenner, 1991; Gherna et al., 1991). It is unusual (with respect to the Enterobacteriaceae) in its inability to grow on MacConkey agar and to reduce nitrates. It grows optimally at 30°C, with a range from 15 to 35°C. A description of biochemical characteristics associated with *A. nasoniae* can be found in Gherna et al. (1991). The optimal pH range for growth is 7.2–7.8, with a pH range from 6.2 to 8.7 (Brenner, 1991). Limited antibiotic susceptibility studies indicate that *A. nasoniae* is resistant to polymyxin, penicillin, methicillin and erythromycin and is sensitive to gentamicin, chloramphenicol, tetracycline and sulfathiazole (Werren et al., 1986). Growth does not occur in minimal salts plus glucose without the addition of protein digests; amino acid supplements do not support growth. Vitamins, trace metals, and IsoVitalex also do not support growth (Brenner, 1991). The addition of 1% proteose peptone (Difco no. 0120) to conventional media, however, has been shown to improve growth (Gherna et al., 1991). “*Candidatus Arsenophonus triatominarum*” is also Gram negative, nonmotile, and non-sporeforming (Hypša and Dale, 1997). The rods are highly filamentous (>15 μ m in length, 1–1.5 μ m in diameter).

Both *A. nasoniae* and *Candidatus Arsenophonus triatominarum* are maternally transmitted, and both are found in the central nervous system (brain and neural ganglia) of infected insects. *Candidatus Arsenophonus triatominarum* is additionally found in the hemolymph, heart, salivary glands, visceral muscles, nephrocytes, ovaries, testes and dorsal vessels of *T. infestans* (Hypša and Dale, 1997). A sex-ratio distorter trait due to.

Candidatus Arsenophonus triatominarum has not been found in *T. infestans*.

The type strain of *A. nasoniae* is SKI4 (= ATCC 49151).

Brenneria

The genus *Brenneria* is composed of several necrogenic phytopathogenic species that formerly resided within the “amylovora group” of the genus *Erwinia*. Phylogenetic investigations conducted on 16 *Erwinia* species utilizing 16S rDNA sequence data identified four distinct clusters, one of which (cluster IV) contained the species *E. salicis*, *E. nigrifluens* and *E. rubrifaciens* (Kwon et al., 1997). Hauben et al. (1998a) analyzed the 16S rDNA sequences of 29 plant-associated strains and also identified four clusters. In this later study, cluster III contained the three species previously found to reside in cluster IV by Kwon et al. (1997), in addition to *E. alni*, *E. paradisiaca* and *E. quercina*. These six species shared sequence similarities ranging from 94.7–97.4%. The mean sequence relatedness of cluster IV members to the genera *Erwinia* and *Pectobacterium* were 94.5 and 95.4%, respectively (Hauben et al., 1998a). Signature sequences identified among cluster III members were conserved in all six species; these sequences differed from those of cluster I (*Erwinia*), cluster II (*Pectobacterium*) and cluster IV (*Pantoea*). Based upon these results, Hauben et al. (1998a) proposed the transfer of these six *Erwinia* species to a new genus, *Brenneria*, named in honor of the American bacteriologist Don J. Brenner. Subsequent studies investigating sequence divergence in the glyceraldehyde-3-phosphate dehydrogenase (*gapDH*) gene of the glycolytic pathway support the genetic differentiation of the genera *Brenneria* and *Erwinia* (Brown et al., 2000). However, other phylogenetic studies have not demonstrated such a robust separation between *Brenneria* and *Pectobacterium* species (Spröer et al., 1999). At the DNA level, *E. salicis*, *E. nigrifluens* and *E. rubrifaciens* are 27–32% related to *E. quercina* EQ 102; *E. rubrifaciens*, *E. nigrifluens* and *E. quercina* are 33–60% related to *E. salicis* ATCC 15712 at 60°C (Brenner et al., 1974). Similar relatedness values have been reported using *E. nigrifluens* (29–47%) and *E. rubrifaciens* (25–

54%) as labeled DNA. The G+C content of members of the genus *Brenneria* range from 50.1 to 56.1 mol% (Hauben et al., 1998a).

The genus *Brenneria* consists of Gram-negative, oxidase-negative, catalase-positive fermentative rods, 1.3–3.0 µm in length by 0.5–1.0 µm in width (Hauben et al., 1998a). Biochemically, *Brenneria* species are similar to *Pantoea*, *Pectobacterium* and *Erwinia* in that they fail to produce arginine dihydrolase and to decarboxylate amino acids such as ornithine and lysine (Lelliott and Dickey, 1984). Acid is produced from the fermentation of D-glucose, D-fructose, salicin, mannose and sucrose. Amylases are not produced. *Brenneria rubrifaciens* produces a pink diffusible pigment on YDC medium (1% yeast extract, 1% D-glucose, 2% precipitated chalk, and 2% agar). Most species are sensitive to carbenicillin, cephalothin, chloramphenicol, naladixic acid and tetracycline, and resistant to bacitracin, erythromycin and gentamicin. Differential characteristics useful in separating members of the genus *Brenneria* are listed in Table 2.

As former members of the *Erwinia* “amylovora group,” *Brenneria* species cause dry necrosis or wilt in the specific host plants they infect. *Brenneria alni* causes necrotic cankers in the bark of the trunk, branches and twigs of the Italian alder (*Alnus cordata*) and black alder (Surico et al., 1996). In the warmer months, a watery liquid is expressed from small cracks in the canker. A similar disease called “drippy nut disease” is caused by *B. quercina* in oaks. *Brenneria nigrifluens* causes bark canker in the Persian (English) walnut, while *B. rubrifaciens* causes necrosis in the Persian walnut (*Juglans regia*). *Brenneria salicis* is the causative agent of “watermark disease” in willows (*Salix* sp.). This vascular wilting disease is characterized by the appearance of wilted, dried, brown-colored leaves (Hauben et al., 1998b). Infection primarily resides within the xylem vessels of infected trees.

The type strains of *Brenneria* species are listed in Table 3.

Buchnera

The genus *Buchnera* consists of a single species, *B. aphidicola*, which is an obligate intracellular symbiont of the greenbug aphid, *Schizaphis graminum* (Munson et al., 1991). *Buchnera aphidicola* cannot be cultured in vitro. The bacterium exists within 60–80 huge specialized aphid cells called “bacteriocytes” or “mycetocytes” located within host-derived membrane vesicles termed “symbiosomes” (Baumann et al., 1995). *Buchnera* is vertically transmitted to eggs and offspring by a process that is not completely understood, thereby perpetuating the association between bacterium and insect. *Buchnera* or *Buchnera*-like endosymbionts also have been reportedly found in a number of aphid species including *Rhopalosiphum maidis*, *Rhopalosiphum padi*, *Myzus persicae*, *Uroleucon sonchi*, *Acyrtosiphon pisum*, *Diuraphis noxia*, *Chaitophorus viminalis*, *Mindarus victoria*, *Pemphigus betae* and *Melaphis rhois* (Munson et al., 1991); some species of the tribe Cerataphidini are devoid of *Buchnera* endosymbionts (Baumann et al., 1995).

Based upon 16S RNA sequence data, *Buchnera* belongs to the γ -3 subdivision of the class Proteobacteria and is most closely related to members of the family Enterobacteriaceae (Munson et al., 1991; Baumann et al., 1995). The G+C content of *Buchnera* DNA is 30 mol%. *Buchnera aphidicola* appears to have developed a symbiotic association with a progenitor aphid species approximately 150–200 million years ago (Buades et al., 1999). The genome (630–643 kb) is only about one-seventh the size of *E. coli* (Wernegreen et al., 2000). However, the size of *Buchnera* genomes recovered from different aphid species is highly conserved (<3% difference), suggesting genome shrinkage early in the evolutionary symbiotic process. Multiple copies of the genome (>120) exist within bacteriocytes (Komaki and Ishikawa, 1999). This copy number varies depending upon the developmental stage of the aphid, increasing from post-embryonic development (0.2 times; 10^6 endosymbionts) to adulthood (5.6×10^6 endosymbionts) and subsequently declining with age (Baumann et al., 1998; Komaki and Ishikawa, 2000).

Buchnera aphidicola consists of round to oval cells (2–5 μ m in diameter) that have the general morphology of a Gram-negative cell wall lacking a flagellum (Munson et al., 1991). There is both ultrastructural and chemical evidence of the presence of peptidoglycan between two unit membranes (Baumann et al., 1995) but polyamines, with the exception of spermidine, are missing (Nakabachi and Ishikawa, 2000).

The complete genome of *Buchnera* strain APS (640,681 bp) from the pea aphid, *Acyrtosiphon pisum*, has recently been sequenced (Shigenobu et al., 2000). A total of 583 open-reading frames (ORFs) were identified. The chromosome contains genes for the amino acid biosynthesis (histidine, serine and branched-chain families), fatty acid biosynthesis and polyamine biosynthesis (Shigenobu et al., 2000). However, it either lacks or is deficient in genes required for the synthesis of cell-surface components, including lipopolysaccharides and phospholipids, necessitating their symbiotic association with aphids (Shigenobu et al., 2000). Other *Buchnera* genes detected include those involved in DNA replication, energy metabolism, cell division, chaperons, colicin-related functions and protein translation and modification (Baumann et al., 1998; Shigenobu et al., 2000). An integrated view of *Buchnera* metabolism can be found in Shigenobu et al. (2000). Another unusual feature of the *Buchnera* genome is the presence of a single copy of the genes (16S, 23S-5S) coding for rRNA (Baumann et al., 1998). The presence of a single ribosomal gene copy is indicative of slow-growing organisms. Acetone preservation appears to be the method of choice for preserving *Buchnera* DNA in preparation for molecular analysis (Fukatsu, 1999).

Aphids primarily feed on plant phloem sap (Baumann et al., 1995). This diet is rich in carbohydrates but deficient in nitrogenous compounds. Aphids cannot synthesize 10 essential amino acids for growth (Baumann et al., 1998). Such nutrients (e.g., tryptophan and leucine) are provided by *Buchnera* endosymbionts (Baumann et al., 1995). *Buchnera* endosymbionts furnish these essential nutrients by plasmid-mediated amplification of key genes involved in tryptophan and leucine biosynthesis (Van Ham

et al., 2000). If aphids are treated with antibiotics to eliminate endosymbionts, they lose the ability to reproduce, and die prematurely (Baumann et al., 1998). Thus, the symbiotic association between aphids and *Buchnera* is essential for life.

Under Rule 18a of the *International Code of Nomenclature of Bacteria*, when a species cannot be maintained in culture, a description may serve as the type strain. On this basis, the type strain has been designated as a primary endosymbiont of *Schizaphis graminum* (Munson et al., 1991).

Budvicia

The genus *Budvicia*, with its single species *B. aquatica*, was first isolated and described by Aldová and colleagues in Czechoslovakia in 1983 (Brenner, 1991). DNA relatedness studies on these strains and a formal genus and species proposal were subsequently reported collaboratively by the Czech group and a group at the Pasteur Institute in Paris (Bouvet et al., 1985; Brenner, 1991). Phylogenetic analysis of the type strain of *B. aquatica* indicates that *Budvicia* forms a distinct lineage in the family, well separated from other Enterobacteriaceae genera (Spröer et al., 1999). Sources from which *B. aquatica* has been isolated include fresh water sources (wells, water pipes, swimming pools, brooks, streams and rivers), sewage water samples, and from one shrew in Spain (Brenner, 1991; Schubert and Groeger-Söhn, 1998).

Relatedness of the other 59 strains to the type strain of *B. aquatica* was 71–100% (87% average) in 60°C DNA hybridization reactions, and divergence in related sequences was 0.0–0.2% (Brenner, 1991). Several *Budvicia*-like strains were only 9–22% related to the *B. aquatica* hybridization strain 23227HG26. Relatedness of *B. aquatica* to other Enterobacteriaceae was 8% or less. The G+C content is 46 mol% (Bouvet et al., 1985). *Budvicia aquatica* expresses the ECA (Böttger et al., 1987).

A medium has been designed for the recovery of *B. aquatica* from environmental water samples (Schubert and Groeger-Söhn, 1998).

Medium of Schubert and Groeger-Söhn (1998) for the Recovery of *B. aquatica*

Trypticase peptone	15.0 g
Soybean peptone	5.0 g
Sodium chloride	5.0 g
Sodium thiosulfate (5H ₂ O)	10.0 g
Ferric ammonium citrate	2.0 g
Sodium deoxycholate	1.5 g
Agar	15.0 g

Dissolve ingredients in 1 liter of deionized water and adjust pH to 7.3.

To the basal medium, 7.0 µg/ml of cephalothin (sodium salt) is added. Hydrogen sulfide (H₂S)-positive colonies are picked and identified as *B. aquatica* biochemically. In a study of water samples taken from rivers, streams and wastewater, *B. aquatica* was detected in low numbers (range 0.3–1.3 colony forming units (cfu)/ml) in all surface water samples analyzed (Schubert and Groeger-Söhn, 1998). An inflow water sample from a wastewater plant yielded *B. aquatica* at a concentration of 1250 cfu/ml.

Budvicia aquatica grows on MacConkey agar and nutrient agar at 30 and 37°C, respectively, but no growth occurs at 42°C (Brenner, 1991). At 24 h on nutrient agar, *B. aquatica* colonies are small in size (~0.1 mm) increasing to 1.5 mm in diameter after 48 h incubation at 37°C. The bacterium is motile at 22°C with variable motility at 37°C (Aldová et al., 1984). A distinguishing feature of *B. aquatica* is the production of H₂S, and it must be separated from other H₂S-producing members of the family Enterobacteriaceae (Table 4). Other phenotypic properties of the genus *Budvicia* include hydrolysis of urea and production of the enzyme β-galactosidase (the presence of which is indicated by hydrolysis of ONPG, *o*-nitrophenyl-β-D-galactopyranoside). Little or no gas is produced from the fermentation of carbohydrates. A detailed list of pheno-

typic properties can be found in Bouvet et al. (1985).

The type strain of *B. aquatica* is 20186HG01 (= ATCC 25567).

Buttiauxella

The genus *Buttiauxella* consists of seven named species whose primary ecologic niche appears to be as inhabitants of mollusks (Müller et al., 1996). The genus was initially defined by Ferragut and others in 1981 when a taxon previously designated “group F” was formerly proposed as a new genus, *Buttiauxella*, with a single species, *B. agrestis*. However, from the early onset it was clear that additional unrecognized species within the genus existed. Over a decade later, the genus was amended to include six additional species based upon the analysis of over 200 snail and slug strains (Müller et al., 1996). A number of these new species had been previously recognized by the Centers for Disease Control and Prevention (CDC) as separate taxa within the family Enterobacteriaceae and had been given the vernacular names “Enteric Groups 59, 63 and 64.”

The DNA relatedness of strains residing within each *Buttiauxella* species ranges from 68 to 100% at 60°C (Müller et al., 1996). Interspecies DNA-DNA relatedness values varied from 48 to 70% with highest similarity values noted between *B. agrestis* and *B. izardii* and between *B. gaviniae* (Enteric Group 64) and *B. noackiae* (Enteric Group 59). DNA relatedness between *Buttiauxella* and more than 50 other species of Enterobacteriaceae varied from 15 to 30% (Müller et al., 1996). Sequencing of 16S rDNA from all seven species indicates a high degree of phylogenetic relatedness (99.1–99.7%) with much lower similarity values (>97%) recorded between *Buttiauxella* and other genera in the family (Spröer et al., 1999). The G+C content of *Buttiauxella* is 55–57 mol% (Gavini et al., 1983b). *Buttiauxella agrestis* expresses the ECA (Böttger et al., 1987).

The primary habitat of most *Buttiauxella* species appears to be mollusks including slugs and snails. *Buttiauxella* has also been recovered from drinking water, soil and earthworms (Müller et al., 1996). One species (*B. noackiae*, Enteric Group 59) has been recovered from clinical (respiratory tract and wound) specimens and from food (Farmer et al., 1985); however, there is no evidence that *B. noackiae* was involved in clinical disease in any of the patients whose samples yielded this bacterium.

Buttiauxella grows well on ordinary plating media over a 4–37°C range (Janda and Abbott, 1998). Optimal growth occurs between 30 and 36°C. On nutrient agar, colonies are 1–2 mm in

diameter at 24 h and 2–3 mm in size at 48 h (Müller et al., 1996). Poor to moderate growth occurs at 42°C (*B. brennerae* fails to grow at 42°C). Phenotypically, the genus *Buttiauxella* most closely resembles *Kluyvera* (Brenner, 1991; Janda and Abbott, 1998). These two genera are most easily distinguished from one another by a combination of tests listed in Table 5.

Buttiauxella species are H₂S-negative and separation from other H₂S-negative members of the Enterobacteriaceae that inhabit aquatic ecosystems (such as *Budvicia aquatica* [20% are H₂S-negative], *Enterobacter amnigenus*, *Enterobacter intermedius*, *Klebsiella planticola*, *Klebsiella terrigena*, *Rahnella aquatilis* and *Serratia fonticola*) can be problematic. Diagnostic keys to separate these genera and species can be found in Janda and Abbott (1998). Tests useful in the identification of *Buttiauxella* species can be found in Table 6. It should be remembered that in identifying *Buttiauxella* isolates to species level, a battery of biochemical tests is needed. This is due to the fact that no single biochemical test is differential for certain pairs of *Buttiauxella* species, such as *B. agrestis* and *B. izardii*.

In addition to the properties described in Table 6, there are several other noteworthy phenotypic properties of *Buttiauxella* species. Strains of *B. noackiae* segregate into two distinct phenotypes. All snail isolates have been found to be lactose-negative, while 7 of 8 human isolates (Enteric Group 59) are lactose-positive (Müller et al., 1996). *Buttiauxella warmboldiae* strains are initially *m*-inositol positive (Table 6); however, they lose their ability to ferment this non-carbohydrate compound upon prolonged storage (years), suggesting that the fermentation of this compound is not constitutively expressed. Limited susceptibility studies have been performed on *B. agrestis* (Freney et al., 1988). The results of testing 13 *B. agrestis* strains by broth microdilution indicates that the species is resistant to ampicillin, amoxicillin-clavulanic acid, ticarcillin, cephalothin, cefoxitin, cefotaxime, doxycycline, trimethoprim and chloramphenicol, based upon MIC₉₀ values. MIC₅₀ data indicates that many

isolates, however, are susceptible to the above agents with the exception of ticarcillin, cephalothin and trimethoprim. *Buttiauxella agrestis* strains were universally susceptible to the aminoglycosides (gentamicin, tobramycin and amikacin).

The type strains of *Buttiauxella* species are listed in Table 7.

Calymmatobacterium

In 1913, Arag o and Vianna cultured pleomorphic bacteria from ulcerative donovanosis (granuloma inguinale) lesions and named the isolated bacterium “*Calymmatobacterium granulomatis*” (also referred to as “*Donovania granulomatis*”). These cultured bacteria were probably not the causative agent of the disease, and no extant type strain of the species exists (Dienst and Brownell, 1984; Carter et al., 1999a); however, the name has persisted and appears on the *Approved Lists of Bacterial Names* (Skerman et al., 1980). *Calymmatobacterium granulomatis* cannot be cultured in vitro using standard microbiologic techniques and has only been isolated on rare occasions using specialized assays. Amplified genomic DNA from *C. granulomatis* extracted from tissue biopsy specimens or from coculture with monocytes hybridizes with universal Gram-negative but not Gram-positive probes (Kharsany et al., 1999). 16S rDNA sequencing

indicates that *C. granulomatis* contains signature sequences present in members of the γ subclass of Proteobacteria. DNA sequences encoding the *phoE* gene (344 bp) have been amplified from ulcerative material from three patients with the clinical diagnosis of donovanosis. These *phoE* sequences are most closely related to *Klebsiella* species, in particular, *K. ozaenae* (0.3% divergence), *K. pneumoniae* (0.6% divergence), *K. rhinoscleromatis* (1.16% divergence) and *K. oxytoca* (7.8% divergence); they are less related (>25.8% divergence) to other enterobacteria (Bastian and Bowden, 1996). Other studies support close nucleotide similarities (99.7–99.8%) between the *phoE* genes (1001 bp) of *C. granulomatis*, *K. rhinoscleromatis* and *K. pneumoniae* (Carter et al., 1999a). 16S rRNA sequences (1088 bp) are also highly related between these three species (98.8–99.8%), although one study (Kharsany et al., 1999) found lower 16S rDNA similarity values between *C. granulomatis* and *K. pneumoniae* (95%) and *Enterobacter* (94%) than those described by Carter et al. (1999a). Based upon the cited phylogenetic data and the similarity in disease presentation between *C. granulomatis* and *K. rhinoscleromatis*, the proposal has been made to transfer *C. granulomatis* to the genus *Klebsiella* as *K. granulomatis* comb. nov. (Carter et al., 1999a). Because of inability to perform DNA-DNA hybridization studies, the mol% G+C content of *C. granulomatis* is not available.

Humans are the only known reservoir for *C. granulomatis*. Although *C. granulomatis* was reputedly isolated from both embryonated eggs and in cell-free culture medium in studies conducted between 1943 and 1962, recent investigations have failed to confirm these earlier observations. *Calymmatobacterium granulomatis* has been grown in vitro by cocultivation of amikacin-treated tissue biopsy specimens from genital ulcers of patients with a clinical picture of granuloma inguinale with peripheral blood monocytes (Kharsany et al., 1996). These studies have been expanded by other investigators using either HEP-2 cells or monocytes (Carter et al., 1997; Kharsany et al., 1997). Often antimicrobial agents such as cycloheximide, vancomycin, benzylpenicillin and metronidazole are added to prevent the growth in coculture of contaminant microorganisms that are present in tissue biopsy specimens.

Calymmatobacterium granulomatis is a highly pleomorphic Gram-negative rod (Dienst and Brownell, 1984). Morphologic varieties of the bacterium can range from immature forms ovoid to elliptical in shape (0.6–1.0 µm in length), to mature curved-to rod-shaped bacteria 0.5–1.5 µm in width to 1.0–2.0 µm in length. Extracellular bacteria grown in cocultures yield bacilli with bulging or tapered ends exhibiting single or bipolar staining with Giemsa (Kharsany et al., 1997). Giemsa staining also reveals a halo surrounding mature bacilli indicating the presence of a capsule. Encapsulation has been confirmed by ultrastructural investigations. Transmission electron micrographs of *C. granulomatis* bacilli indicate a typical Gram-negative cell wall with an outer membrane, a middle opaque layer, and an inner plasma membrane (Kharsany et al., 1997). Although *C. granulomatis* is a Gram-negative bacterium, it stains poorly with Gram reagents.

Identification of *C. granulomatis* in genital ulcers has been traditionally dependent upon demonstrating the presence of Donovan bodies in infected mononuclear cells or histiocytes (Richens, 1991). Donovan bodies can be visualized using a number of staining techniques including Wright's stain and Giemsa stain. They typically appear as pleomorphic bodies (see above) with bipolar staining giving a closed "safety-pin" appearance. The sensitivity of the technique is 60–80% depending upon the stage of the disease and the type of smear or specimen analyzed (Richens, 1991). Donovan bodies must be distinguished from other intracellular bodies or inclusions, such as rhinoscleroma, leishmaniasis, lymphogranuloma venereum, histoplasmosis, chronic lymphocytic cervicitis and malakoplakia (Richens, 1991). Coculture provides a second alternative method for detecting and visualizing intracellular and extracellular *C. granulomatis*

(Kharsany et al., 1996; Carter et al., 1997; Kharsany et al., 1997). Recently, PCR probes have been developed to detect *C. granulomatis* using swabs rather than biopsy/tissue smears (Carter et al., 1999b). The specificity of the assay is based upon two unique base changes in the *phoE* gene of *C. granulomatis*, which eliminates *Hae*III restriction sites and results in a 167-bp PCR product that is present in *C. granulomatis* but not closely related to the corresponding DNA segment in *Klebsiella* species (Carter et al., 1999b). A colorimetric adaptation of this PCR assay has been developed for routine use in diagnostic laboratories (Carter and Kemp, 2000). All 14 specimens from persons with donovanosis gave strong colorimetric readings while eight unrelated genital specimens were negative.

Donovanosis (granuloma inguinale) is a chronic ulcerative disease of the genitalia and is most commonly seen in tropical climates such as is found in southeast India, the Caribbean, South America, regions of Africa, and in southern China (Richens, 1991; Hart and Rao, 1999). It is thought that *Calymmatobacterium granulomatis* is sexually transmitted. The typical incubation period ranges from 3 to 90 days (1–6 weeks). Four major patterns of donovanosis presentation and disease progression have been identified (Hart and Rao, 1999). These include 1) ulcerative or ulcero-granulomatous disease (the most common pattern), 2) the necrotic or phagedenic type seen in persons with long-standing donovanosis, 3) the hypertrophied type, and rarely, 4) the sclerotic type. Although the genitalia are the most common sites of infection, distal sites may also become infected, such as the neck and mouth (Richens, 1991). Despite the fact that susceptibility studies on *C. granulomatis* cannot be performed, the disease responds to a wide variety of antimicrobial agents, including tetracycline compounds, macrolides, chloramphenicol, and co-trimoxazole (Richens, 1991; Hart and Rao, 1999).

No type strain of *C. granulomatis* currently exists.

Cedecea

The genus *Cedecea* contains three named and two unnamed species, all of which were formerly placed in Enteric Group 15 on the basis of their positive lipase reaction and resistance to colistin and cephalothin (Grimont et al., 1981; Brenner, 1991). DNA relatedness studies revealed five hybridization groups in the 17 strains originally tested. Nine strains were *Cedecea davisae*, five were *Cedecea lapagei*, and one each represented unnamed *Cedecea* species (Brenner, 1991). In the original publication, the unnamed species

were called *Cedecea* species “001,” “002,” and “012.” Subsequently, *Cedecea* species 001 was referred to as “*Cedecea* species 3,” *Cedecea* species 002 as “*Cedecea* species 4,” and *Cedecea* species 012 as “*Cedecea* species 5” (Farmer, 1984; Farmer et al., 1985; Brenner, 1991). A second strain of *Cedecea* species 4 was isolated from blood cultures of a patient with possible endocarditis, and *Cedecea* species 4 was then named “*Cedecea neteri*” (Farmer et al., 1982). A strain possibly representing a sixth *Cedecea* species was isolated from ulcers on the right heel and the left ankle of a 79-year-old man with a history of diabetic arthritis of both legs (Hansen and Glupczynski, 1984). The G+C content is 49–50 mol% for *C. davisae*, 48–52 mol% for *C. lapagei*, and unknown for *C. neteri* (Brenner, 1991). All nomenspecies and *Cedecea* species 3 and 5 produce the ECA (Ramia et al., 1982; Böttger et al., 1987).

Originally, all *Cedecea* isolates had been recovered from humans (Brenner, 1991). However, *Cedecea lapagei* (n = 1) and a *Cedecea* species (n = 1) were subsequently isolated from laboratory-reared oriental fruit flies, *Dacus dorsalis* (Jang and Nishijima, 1990). One strain of *C. davisae* has also been isolated from imported vegetables (Österblad et al., 1999). In a study of *Cedecea* strains received by the CDC, over 70% of the 34 culture-collection isolates were recovered from either the respiratory tract or wounds (Farmer et al., 1985). Other less common anatomic sites yielding *Cedecea* species included blood, stool, urine, gall bladder and eye (Brenner, 1991). The medical significance of *Cedecea* is difficult to assess since most isolates have been recovered from polymicrobial processes and from persons that are severely immunocompromised. *Cedecea davisae*, the most commonly isolated *Cedecea* species, has been isolated from the greatest variety of anatomical specimens (Brenner, 1991; Janda and Abbott, 1998). Bae and Sureka (1983) reported on a scrotal abscess infection in a 50-year-old man with alcoholic hepatitis caused by *C. davisae*. Drainage and culture yielded heavy growth of *C. davisae* and only rare *Staphylococcus epidermidis* colonies. *Cedecea davisae* has also been associated with bacteremia in a 70-year-old man with heart and chronic obstructive pulmonary disease (Perkins et al., 1986). In this case, the role of *C. davisae* is less clear since the patient initially suffered from *S. aureus* bacteremia upon admission (day 4) and was only culture-positive for *C. davisae* from blood, central venous pressure catheter, and Swan-Ganz tips at day 26 of hospitalization. *Staphylococcus epidermidis* was also cultured from the same catheter tips and blood further clouding the issue. An interesting sidelight is the fact that light growth of *C. davisae* was also obtained on

successive days from sputum cultures on this patient during his septic episode, although the clinical picture did not suggest pneumonia. *Cedecea lapagei* has been exclusively recovered from respiratory tract specimens (throat, sputum and lung); for five of these isolates, no clinical information is available (Grimont et al., 1981). A sixth isolate has been recovered from a 60-year-old male with pulmonary disease and a past history of pulmonary tuberculosis and a cavitory lesion consistent with a fungus ball (Coudron and Markowitz, 1987). Although *C. lapagei* was isolated from two lung tissue specimens (pure culture), bronchial washings, and two sputum samples, an etiologic role in the patient’s respiratory problems could not be established. Probably the best evidence for a pathogenic role for *Cedecea* in human disease stems from two case reports concerning *C. neteri* infection. Farmer et al. (1982) described a case of *C. neteri* bacteremia in a 62-year-old man with heart disease and possible endocarditis. Three sets of blood cultures (taken at different times) were positive for *C. neteri*. More recently, a fatal case of *C. neteri* bacteremia has been reported in a 27-year-old woman with systemic lupus erythematosus (Aguilera et al., 1995). In this case report, three sets of blood cultures were positive for *C. neteri* during a septic crisis that the patient experienced 36 days after admission to the hospital. This nosocomial infection was thought to have been involved in the fulminant outcome leading to the patient’s death on the 42nd day of hospitalization. *Cedecea* species 3 has been isolated from post-mortem heart blood of a 76-year-old man who suffered from ethanol dependency, chronic and acute pancreatitis, and micronodular cirrhosis of the liver (Mangum and Radisch, 1982). *Candida albicans* sepsis was the apparent cause of death. No significance to the blood isolate of *Cedecea* species 3 could be ascribed. *Cedecea* species 3 has also been isolated from a wound and the respiratory tract (Farmer et al., 1985). The only isolate of *Cedecea* species 5 was from a wound.

Cedecea superficially resemble *Serratia* in their ability to elaborate lipase and their resistance to colistin and cephalothin (Brenner, 1991). *Cedecea* can be separated from other members of the Enterobacteriaceae by negative tests for lysine decarboxylase, gelatinase, and deoxyribonuclease, their inability to ferment L-arabinose and L-rhamnose and a positive arginine dihydrolase test (Janda and Abbott, 1998). The gelatinase and deoxyribonuclease reactions clearly separate *Cedecea* from *Serratia* (Janda and Abbott, 1998). Differential tests used to identify *Cedecea* species can be found in Table 8.

Certain strains of *Cedecea* emit a distinctive “potato-like” odor, a trait shared with some

<i>C. neteri</i>	002	CDC 0621-75; ATCC 33855

strains of *Serratia*. The potato-like odor is due to a complex mixture of pyrazines (Janda and Abbott, 1998). No formal studies have been published on the antimicrobial susceptibility of *Cedecea* species. What little information is available comes from individual case reports. Most strains appear to be resistant to both ampicillin and first-generation cephalosporins and susceptible to trimethoprim-sulfamethoxazole, tetracycline, ticarcillin and the aminoglycosides (Janda and Abbott, 1998). Susceptibility to second- and third-generation cephalosporins was variable.

The type strains of *Cedecea* species are listed in Table 9.

Ewingella

Enteric Group 40 contained 10 strains from human clinical specimens that were thought to resemble a lipase-negative *Cedecea* biogroup (Brenner, 1991). DNA relatedness showed that these strains constituted a single new species (Grimont et al., 1983). At 60°C, nine of these strains were 86 ± 10% related to the type strain, CDC 1468-78. The new species was 21% or less related to other Enterobacteriaceae (closest species *Rahnella aquatilis*) by the S1 nuclease-trichloroacetic acid (TCA) method. Enteric Group 40 was placed in a new genus *Ewingella* as *Ewingella americana*. The change in melting temperature (ΔT_m) values between eight *E. americana* strains and strain CDC 1468-78

ranged from 1.2 to 2.5°C (Grimont et al., 1983). However, a ninth strain (CDC 0679-79) exhibited a ΔT_m value of 5.5°C, suggesting that a possible subspecies within *E. americana* may exist. The G+C content is 54 mol% (Grimont et al., 1983). *Ewingella americana* produces the ECA (Böttger et al., 1987).

The ecologic niches that *E. americana* inhabits have dramatically expanded over the past decade. Farmer et al. (1985) described a CDC collection of 44 strains, most of which originated from respiratory sources (n = 18), blood (n = 11) or wounds (n = 7). All strains were isolated from humans, with the exception of one food isolate. Pumpuni and others (Pumpuni et al., 1993) have since reported the isolation of *E. americana* from the intestinal tract of a laboratory colony of mosquitoes (*Anopheles stephensi*). A study of 282 mollusks by Müller et al. (1995) resulted in the recovery of 23 strains of *E. americana* from slugs (primarily) and snails. However, since most of the mollusks were not found to harbor *E. americana*, it does not appear to be part of the normal intestinal flora of slugs and snails. Thirty-five strains of *E. americana* have also been isolated from the cultivated mushroom, *Agaricus bisporus* (Inglis and Peberdy, 1996). One mushroom strain (P198) was found to be 88.8% related to the type strain of *E. americana* using a DNA filter hybridization technique.

Ewingella americana is a peritrichously flagellated Gram-negative rod (1.0–1.8 µm in length by 0.6–0.7 µm in width) with characteristics typical of other members of the Enterobacteriaceae. Growth occurs between 15–37°C but not at 40°C (Grimont et al., 1983). *Ewingella americana* grows in peptone water containing 8% NaCl at 30°C. Although *E. americana* was initially thought to be phenotypically similar to a lipase-negative biogroup of *Cedecea*, it can be distinguished from the latter group in that *Ewingella* is malonate-negative, fails to produce gas from glucose fermentation, and is DL-lactate-

negative, while *Cedecea* is positive for all of these traits. However, *Ewingella* needs to be separated from other genera within the Enterobacteriaceae that are H₂S-negative, lysine decarboxylase- and ornithine decarboxylase-negative, and arginine dihydrolase-negative (Table 10).

In the original publication of Grimont et al. (1983), two biotypes of *E. americana* were described. Biogroup 1 strains, which contained nine isolates, were negative for acid production from L-rhamnose, D-sorbitol and D-xylose and were β -xylosidase-negative. Biogroup 2, which contained only a single strain (CDC 0679-79), was positive for all of these characteristics. Since this publication, no additional strains of biogroup 2 have been isolated, although strains have been recovered that are positive for one or more of the above characters but not all four (Devreese et al., 1992). Another interesting observation is the fact that strains of *E. americana* initially isolated from mollusks and mushrooms have been lipase-positive on Tween 80 medium (Müller et al., 1995; Inglis and Peberdy, 1996). In one of these studies, lipase activity was lost upon subculture suggesting that the enzyme is not constitutive (Müller et al., 1995). Chitinolytic activity has been detected in the type strain of *E. americana* and in other strains isolated from mushrooms (Inglis and Peberdy, 1996). Nitrate-negative strains of *E. americana* are also known to occur (McNeil et al., 1987a). Some strains of *E. americana* contain from one to four plasmids ranging in molecular mass from ~3 to 190 MDa (McNeil et al., 1987a). Freney et al. (1988) studied the susceptibility of six *E. americana* strains to a variety of antimicrobial agents. Based upon MIC₅₀ data, at least some strains were found resistant to or had reduced susceptibility for ampicillin, β -lactamase-inhibitor combinations, cephalothin, cefoxitin, ticarcillin, chloramphenicol, doxycycline and trimethoprim; all six strains were susceptible to the aminoglycosides and to cefotaxime. *Ewingella americana* strains appear to have wide-

spread or universal resistance to ampicillin, first-generation cephalosporins and cephamycins, based upon individual case reports.

Ewingella americana appears to be a rare human pathogen, more frequently being associated with cases of polymicrobial bacteremia, pseudobacteremia, or nosocomial outbreaks of septicemia linked to contaminated catheters, ice baths, or coagulation tubes (Pien et al., 1983; Pien and Bruce, 1986; McNeil et al., 1987b). In most of these instances, the original source of *E. americana* appears to be water. The most common underlying theme of persons developing *E. americana* bacteremia has been surgery (Pien et al., 1983; Pien and Bruce, 1986; Devreese et al., 1992). In addition to bacteremia, *E. americana* has been associated with peritonitis in a woman with end-stage renal disease caused by polycystic kidney disease (Kati et al., 1999) and two ocular infections in immunocompetent adults (Heizmann and Michel, 1991; Da Costa et al., 2000). *Ewingella americana* also appears to be a possible causative agent of internal stipe necrosis (Inglis and Peberdy, 1996). This disease causes a browning disorder of the cultivated mushroom, *Agaricus bisporus*.

The type strain of *E. americana* is CDC 1468078 (= ATCC 33852 = CIP 8194).

Kluyvera

Asai and colleagues (Asai et al., 1955) studied a group of strains from soil and sewage in Japan that produced large amounts of α -ketoglutaric acid during fermentation of glucose. Six of their strains were peritrichously flagellated and assigned to *Escherichia* and “*Aerobacter*” (Brenner, 1991). Five other strains were thought to be polar flagellates and were placed in the new genus *Kluyvera* in the family Pseudomonadaceae. Two species, “*Kluyvera citrophila*” and “*Kluyvera noncitrophila*” were created based upon the ability to use citric acid (Brenner,

1991). Asai et al. (1962) subsequently confirmed the observation of Shewan and Hugh (cited in Asai et al., 1962) that *Kluyvera* species have peritrichous flagella (Brenner, 1991). They transferred them to *Escherichia*, thus effectively abolishing the genus *Kluyvera*. *Kluyvera* formally lost standing in nomenclature when it was omitted from the *Approved Lists of Bacterial Names* (Skerman et al., 1980).

From 1965 to 1980, some 145 strains that appeared biochemically similar to *Kluyvera* were received for identification at the CDC (Brenner, 1991). They were assigned to Enteric Group 8 (Farmer et al., 1981). DNA relatedness studies on 44 Enteric Group 8 strains indicated three closely related species (60–70% interspecies relatedness). Farmer et al. (1981) revived the genus name *Kluyvera* for these species. Both strains originally designated “*K. noncitrophila*” and two of three designated “*K. citrophila*” by Asai and colleagues were in the same DNA hybridization group (named “*K. cryocrescens*”; the other “*K. citrophila*” strain was in the hybridization group named “*K. ascorbata*”). Since the ability to utilize citrate did not correlate with the genomospecies, Asai’s species names were not revived (Brenner, 1991). One species was named “*Kluyvera ascorbata*” because it produced acid from ascorbate. A second species was named “*Kluyvera cryocrescens*” because it grew and fermented glucose at 5°C (Brenner, 1991). A third genomospecies (*Kluyvera* species 3), which contained five strains, was not named at that time. In 1996, a taxonomic study of *Buttiauxella* and *Kluyvera* strains primarily isolated from human sources and mollusks identified two new *Kluyvera* species (Müller et al., 1996). Strains formerly assigned to *Kluyvera* species 3 (Enteric Group 35/36) were designated “*Kluyvera georgiana*,” while a second previously unrecognized taxa was named “*Kluyvera cochleae*.” All strains within each newly designated species exhibited >70% interspecies relatedness at both 60 and 75°C (Müller et al., 1996). Relatedness to other members of the Enterobacteriaceae ranged from 15 to 30%. The G+C content of *Kluyvera* is 55–57 mol% (Farmer et al., 1981). Both *K. ascorbata* and *K. cryocrescens* produce the ECA (Böttger et al., 1987).

The major habitat(s) of *Kluyvera* species is presently unknown. The CDC culture collection contained 163 *Kluyvera* strains in 1985 (Farmer et al., 1985; Brenner, 1991), a majority of which were *K. ascorbata* (n = 123). Regardless of species designation, most *Kluyvera* strains of human origin were isolated from the respiratory tract, urine and stool in decreasing order of frequency. *Kluyvera* species have also been found in sewage, water, soil samples, a hospital sink, milk and a cow (Farmer et al., 1981). Recently, *Kluyvera*

species have been isolated from new environmental and animal sources. *Kluyvera* species have been isolated from birds including captive raptors (Bangert et al., 1988). Although not probably a major reservoir, *K. cochleae* strains have been recovered from mollusks including snails and a slug (Müller et al., 1996). A 1999 bacteriologic survey looked at the isolation of Enterobacteriaceae from fresh and frozen vegetables. Seven *Kluyvera* isolates were recovered from fresh Finnish and imported vegetables (Österblad et al., 1999).

Kluyvera species are typical members of the family Enterobacteriaceae. Good growth occurs at 30–36°C, with moderate to good growth occurring at 42°C (Müller et al., 1996). Most species do not require amino acids for growth, although some isolates require one or more vitamins (Farmer et al., 1981). Of the four species, *K. cochleae* is the least active metabolically (Müller et al., 1996). Biochemically, *Kluyvera* species most closely resemble *Buttiauxella* from which they must be separated. Both genera possess similar fatty acid patterns with 16:0, 17:0 *cyclo*, and 14:0 predominating (Kämpfer et al., 1997). While no single test clearly separates these two genera, they can be distinguished based upon several biochemical reactions listed in Table 11.

Identification of *Kluyvera* isolates to species level is a difficult process since a number of the most discriminatory tests are not routinely found in diagnostic laboratories. Brenner (1991) recommends several tests that are useful in separating the two most common species, *K. ascorbata* and *K. cryocrescens*, from one another (Table 12).

Kluyvera cochleae can be easily distinguished from any *Buttiauxella* or other *Kluyvera* species since it is indole-negative and Voges-Proskauer-positive (Müller et al., 1996). However, some strains (~33%) of *K. cochleae* are Voges-Proskauer-negative (Farmer, 1999). The most useful tests to separate *K. georgiana* from *K. ascorbata* and *K. cryocrescens* are for L-arginine

and 3-hydroxybenzoate utilization (Müller et al., 1996). Unfortunately, biochemical results on differential tests used to separate *K. ascorbata* from *K. cryocrescens* have not been reported for *K. georgiana* and *K. cochleae* with the exception of dulcitol. Some strains of *K. ascorbata* produce blue and red crystals, termed “kluyveramycin,” upon prolonged incubation at room temperature on trypticase soy agar (Farmer et al., 1981). *Kluyvera ascorbata* CDC strain 2221-78 (ATCC 33434) is a strong producer of kluyveramycin. One of two strains of *K. cryocrescens* has been found to produce pyrrolidonyl peptidase, while neither strain of *K. ascorbata* tested produced this activity (Chagla et al., 1993). Five strains of *K. ascorbata* have been tested for susceptibility to select antibiotics (Frenay et al., 1988). All five strains were found susceptible to ampicillin, ticarcillin, cefoxitin, cefotaxime, doxycycline, and to aminoglycosides; one of five strains was resistant to cephalothin and trimethoprim.

Because of the technical difficulty in identifying *Kluyvera* isolates to species, the exact role each species plays in human disease is largely unknown. West and others (West et al., 1998) have summarized 18 possible cases of *Kluyvera* infection published in the literature since 1980. Of these 18 cases, only 8 of the strains were identified to species level, with an equal distribution between *K. ascorbata* and *K. cryocrescens*. Six of the 18 cases involve diarrheal disease where the association of *Kluyvera* with gastroenteritis is tenuous at best. The issue is further clouded by the fact that *Kluyvera* has been recovered from the gastrointestinal tract of asymptomatic individuals (Fainstein et al., 1981). Most cases of extraintestinal *Kluyvera* infection have involved persons with underlying disease. Only three fatal infections have been reported, two involving the blood and one a case of peritonitis, and it is not clear how much the infection and underlying illness each contributed to these negative outcomes. Tristram and Forbes (1988) reported a case of urinary tract infection and sepsis in an 11-month-old infant with fever, vomiting and lethargy. The infant suffered from bilateral vesicoureteral reflux, and *Kluyvera* (species not

Table 13. Type strains of *Kluyvera* species.

Species	Type strain	Other designations
<i>K. ascorbata</i>	CDC 0648-74	ATCC 33433
<i>K. cryocrescens</i>	CDC 2065-78	ATCC 33435
<i>K. cochleae</i>	S 3/1-49	ATCC 51609; DSM 9406; serial no. 185
<i>K. georgiana</i>	CDC 2891-76	ATCC 51603; DSM 9409; serial no. 189

identified) was recovered from a suprapubic aspirate and from blood. Luttrell et al. described a soft tissue infection of the right forearm in a healthy 37-year-old woman. She apparently acquired her *Kluyvera* infection (species not identified) after cutting herself on the open lid of a can in the garbage. A case of *Kluyvera* pyelonephritis (species not identified) has also been described in a five-year-old girl where >100,000 cfu/ml were recovered from a urine sample (Dollberg et al., 1990); she had no underlying abnormalities. A case of fatal *Kluyvera* mediastinitis (species not identified) has been reported in a 74-year-old man with adult onset diabetes, hypertension, and end-stage renal disease (Sierra-Madero et al., 1990). After undergoing multiple medical procedures including a five-vessel saphenous vein coronary artery bypass and aortic valve replacement, he developed mediastinitis due to *Kluyvera*. *Kluyvera* was recovered from a sternal wound, the sputum, and the blood of this patient. Biochemical test results on this strain did not conform to known characteristics of either *K. ascorbata* or *K. cryocrescens*. Another fatal *Kluyvera* infection involved a case of *K. ascorbata* peritonitis in a 13-year-old girl with Friedreich’s ataxia and a one-year history of weight loss (Yogev and Kozlowski, 1990; West et al., 1998). *Kluyvera ascorbata* was recovered from multiple premortem and postmortem samples including endotracheal tube aspirates, peritoneal fluid, urine (>100,000 cfu/ml), subdiaphragmatic abscesses, and from lung tissue. The latest reported *Kluyvera* infection involved a soft tissue infection of the right middle finger of a 31-year-old man with insulin-dependent diabetes mellitus (West et al., 1998). He abraded his finger while using a chemical stripper on flooring with his bare hands. A painful blister resulted and *K. cryocrescens* was isolated on two separate occasions from debrided tissue.

The type strains of *Kluyvera* species are listed in Table 13.

Leclercia

Tamura et al. (1986) proposed transferring *Escherichia adecarboxylata* to the newly created

Leclercia. *Leclercia adecarboxylata* gives + + – reactions for the IMViC (indole, methyl red, Voges-Proskauer, and citrate) tests and negative reactions for lysine and ornithine decarboxylases and arginine dihydrolase (Brenner, 1991). It was first isolated from foods and named “*E. adecarboxylata*” by Leclerc in 1962, largely on the basis of its IMViC pattern, which is identical to that of *E. coli* (Brenner, 1991).

Little attention was paid to *Escherichia adecarboxylata* until several research groups attempted to clarify the *Enterobacter agglomerans*-*Erwinia herbicola* complex. Gavini et al. (1983b) found that *Escherichia adecarboxylata* strains formed a distinct phenotypic cluster (E₅), separate from all other groups in the *Enterobacter agglomerans* complex. Izard et al. (1985) classified Gavini's groups E₅, E₃ and E₂, and group XI of Brenner et al. (1984) as *Escherichia adecarboxylata* on the basis of DNA hybridization and similar electrophoretic patterns of soluble proteins. In their study, *Escherichia adecarboxylata* was over 60% related to *Enterobacter cloacae*, and they did not recommend taxonomic changes. Tamura et al. (1986) also found that *Escherichia adecarboxylata* was phenotypically distinct from *Enterobacter agglomerans* and that it was a single species by DNA hybridization. In their study, *Escherichia adecarboxylata* was 32% or less related to other Enterobacteriaceae and only 3–5% related to *Enterobacter cloacae*. On the basis of these findings, they transferred *Escherichia adecarboxylata* to *Leclercia* (Brenner, 1991). The marked difference in relatedness of *Leclercia adecarboxylata* to *Enterobacter cloacae* and to other Enterobacteriaceae obtained in the studies of Izard et al. (1985) and Tamura et al. (1986) must be resolved to assess the validity of the genus *Leclercia* (Brenner, 1991). The G+C content is 51–55 mol% (Izard et al., 1985; Tamura et al., 1986). Production of ECA has not been reported.

The first isolates of *Leclercia adecarboxylata* were from foods in France (Brenner, 1991). The 23 strains studied by Izard et al. (1985) were from drinking water (20 strains), humans (2 strains), and a plant source. Of 86 strains reported by Tamura et al. (1986), 58 were from humans including from human sputum, blood, urine, stool and wounds in decreasing order of frequency. *Leclercia* has also been isolated from imported vegetables (Österblad et al., 1999). It appears identical to Enteric Group 41 (Farmer et al., 1985; Temesgen et al., 1997).

Leclercia adecarboxylata is lysine- and ornithine-decarboxylase-negative, fails to produce arginine dihydrolase, and is H₂S-negative. As such, it must be distinguished from other biochemically similar genera within the Enterobacteriaceae such as *Ewingella*, *Moellerella* and

Rahnella (Table 10). The type strain produces a yellow pigment, but most other strains do not (Brenner, 1991). *Leclercia adecarboxylata* colonies resemble those of *E. coli* on MacConkey, desoxycholate-lactose, and eosin-methylene blue agars, and the IMViC reactions are those of *E. coli* (Tamura et al., 1986; Brenner, 1991). Thus, it may be prudent to review any strains identified as decarboxylase-negative *E. coli* (Brenner, 1991). *Leclercia adecarboxylata* produces pyrrolidonyl peptidase (Chagla et al., 1993). From the limited number of reports available in the literature, *L. adecarboxylata* appears to be uniformly susceptible to most commonly administered antibiotics including the aminoglycosides, carbapenems, ampicillin, trimethoprim-sulfamethoxazole, fluoroquinolones and to the cephalosporins (Temesgen et al., 1997). Resistance to fosfomycin was detected in one isolate (de la Obra et al., 1999).

Temesgen and colleagues (Temesgen et al., 1997) have summarized the clinical significance of *L. adecarboxylata*. This involves only a handful of cases. *Leclercia adecarboxylata* was recovered from five patients at the Mayo Clinic between 1984 and 1995. For three of these patients, *L. adecarboxylata* was recovered as part of mixed microbial flora of wound infections involving an abrasion to the right calf while camping, a crush injury to the right foot, and a penetrating nail injury to a toe. The clinical significance of *L. adecarboxylata* in each of these instances could not be determined. A fourth case from this study involved the isolation of *L. adecarboxylata*, along with other Gram-negative flora, from the sputum of a patient with right lower lobe pneumonia. The significance was highly questionable because of the large number of other microbial pathogens isolated simultaneously; however, Temesgen et al. (1997) did describe a case of *L. adecarboxylata* bacteremia in a 35-year-old woman with acute nonlymphocytic leukemia who had recently undergone a bone marrow transplantation. Two other bacteremia cases cited in this review, that of a 45-year-old man with ethanol cirrhosis and an 8½-month-old baby with congenital gastroschisis and intestinal atresia, support the rare role of *L. adecarboxylata* as a bloodborne pathogen. de la Obra et al. (1999) documented a fourth case of *Leclercia* bacteremia in a 42-year-old woman with multiple myeloma who presented with fever after apheresis. *Leclercia adecarboxylata* has also been associated with a case of peritonitis in a 5-year-old boy with end-stage renal disease (Fattal and Deville, 2000). The most recent episodes of *L. adecarboxylata* infection involve a chronically inflamed gallbladder in an elderly woman, and polymicrobial sepsis in an 11-month-old child with acute lymphoblastic leukemia and in an 80-

year-old woman with cardiovascular disease (De Baere et al., 2001; Longhurst and West, 2001). These collective reports indicate that *L. adecarboxylata* is a very rare human pathogen primarily infecting persons that are immunocompromised or with severe underlying illnesses.

The type strain of *L. adecarboxylata* is ATCC 23216.

Leminorella

The genus *Leminorella* was created from 11 H₂S-positive strains previously referred to as "Enteric Group 57" (Hickman-Brenner et al., 1985b; Brenner, 1991). DNA relatedness studies showed three genomospecies. *Leminorella grimontii* contained six strains, three from human stools, one from a mouse stool, and two from urines; *Leminorella richardii* contained four human strains, all from stools; and *Leminorella* species 3 contained a single strain from a human stool. The two named species were 32–49% interrelated (Brenner, 1991). *Leminorella* species 3 was 60% related to *L. grimontii* and 40% related to *L. richardii* (Brenner, 1991). Phylogenetic analysis of the type strain of *L. grimontii* indicates that *Leminorella* forms a distinct lineage in the family, well separated from other Enterobacteriaceae genera (Spröer et al., 1999). The cellular polyamine composition of both species includes acetylspermidine, putrescine, diaminopropane and spermidine (Hamana, 1996). The G+C content of *L. grimontii* is 52 mol%, that of *L. richardii* is 53 mol%, and that of species 3 is 55 mol% (Brenner, 1991). Both *L. grimontii* and *L. richardii* express the ECA (Böttger et al., 1987).

Leminorella is H₂S-positive and must be separated from other rarely encountered H₂S-positive genera in the family Enterobacteriaceae (Table 4). Members of the genus are lysine- and ornithine-decarboxylase negative and arginine dihydrolase negative. *Leminorella* resembles *Proteus* in its positive H₂S reaction and tyrosinase activity and failure to ferment D-mannose, but it is easily distinguished from *Proteus* by its negative urea and phenylalanine deaminase reactions. Biochemically, *Leminorella* most closely resembles *Budvicia* and *Pragia*, however, *Pragia* is motile at 36°C, while *Leminorella* is not (Farmer, 1999). The ability of *Budvicia* to ferment L-rhamnose separates this genus from *Leminorella*. Some strains react weakly in *Salmonella* antisera (Brenner, 1991). *Leminorella* species can be separated from one another on the basis of the following tests in Table 14.

Until recently the clinical significance of *Leminorella* was in doubt (Brenner, 1991). However a 28-month study at the Tel Aviv Sourasky Med-

<i>L. richardii</i>	CDC 0978-82	ATCC 33998

ical Center revealed 18 patients from whom *Leminorella* was isolated for an overall incidence of 11 cases/100,000 admissions (Blekher et al., 2000). For 14 of these patients, medical records were available for review. Using modified CDC criteria for determining clinical significance, five patients were judged to have definite infections caused by *Leminorella* species. Two of these infections were associated with the urinary tract (>100,000 cfu/ml, pyuria), one wound infection involved a fractured tibia, a case of peritonitis in a 75-year-old man, and a case of primary bacteremia in a 10-year-old boy with acute myelocytic leukemia (Blekher et al., 2000). The average age of these 14 patients was 67 years, and most illnesses involved males (78%) and were nosocomial in origin (93%). All patients had other comorbid conditions. In addition to these definite cases (43%), another 50% of the patients were thought to have probable or possible infections caused by *Leminorella* (Blekher et al., 2000).

The type strains of *Leminorella* are listed in Table 15.

Moellerella

In 1984, a group of nine strains previously assigned to Enteric Group 46 by the CDC were shown to exhibit 80–93% interspecies DNA relatedness at 60°C and 78–97% relatedness at 75°C using the hydroxyapatite method (Hickman-Brenner et al., 1984). No other group within the family Enterobacteriaceae, including 49 named and unnamed species, was more than 32% related (*Proteus* and *Providencia*) at 60°C to Enteric Group 46. Even *Proteus* and *Providencia* were only 4–7% related to Enteric Group 46 at the more stringent temperature of 75°C.

Based upon these findings, Enteric Group 46 represented a new genus in the family Enterobacteriaceae and the name *Moellerella wisconsensis* was proposed (Hickman-Brenner et al., 1984). *Moellerella wisconsensis* expresses ECA (Böttger et al., 1987). The G+C content of *M. wisconsensis* has not been determined (Brenner, 1991).

The natural habitat of *M. wisconsensis* is unknown. Most strains have been recovered from human feces. In the original description of the genus, 8 of 9 isolates were of fecal origin, with the remaining strain recovered from drinking water (Hickman-Brenner et al., 1984). Marshall et al. (1986) screened 400 stool samples for *M. wisconsensis* and isolated three additional strains (0.75%).

Medium of Marshall et al. (1986) for the Recovery of *M. wisconsensis*

Proteose peptone No. 3 (Difco)	20.0 g
Lactose	10.0 g
Neutral red	0.075 g
Sodium chloride	5.0 g
Agar	12.0 g
Polymyxin	B30.0 g
Bacitracin	500,000 IU

Dilute up to 1 liter with deionized water and adjust pH.

Other human sources from which *M. wisconsensis* has been isolated include a wound, gall bladder, and respiratory secretions (Wittke et al., 1985; Wallet et al., 1994). *Moellerella wisconsensis* has also been isolated from four captive raptors fed chicken-containing diets (Bangert et al., 1988).

Moellerella wisconsensis is indistinguishable from *E. coli* on MacConkey and eosin-methylene blue agars producing deep pink and dark colonies with a green metallic sheen, respectively (Hickman-Brenner et al., 1984). *Moellerella wisconsensis* has a – + – + IMViC pattern and is negative in tests for urea, phenylalanine-, lysine- and ornithine decarboxylases, arginine dihydrolase, motility, and gas from D-glucose (Hickman-Brenner et al., 1984; Brenner, 1991). Most strains are susceptible to cephalothin, chloramphenicol and gentamicin, and resistant to ampicillin, carbenicillin and colistin; however, definitive susceptibility studies on this bacterium are lacking. *Moellerella* needs to be separated from other H₂S-negative bacteria with similar biochemical characteristics including *Ewingella*, *Tatumella* and *Photorhabdus/Xenorhabdus* (Table 10).

The pathogenicity of *M. wisconsensis* is unknown. Hickman-Brenner et al. (1984) described one case of bloody diarrhea in a 40-year-old physician who developed fever, abdominal pain, and cramps within 48 hours of his arrival in Peru. His stool culture yielded predom-

inant growth of *M. wisconsensis*. Another possible case of infection involved a 71-year-old man with acute cholecystitis that resulted in the isolation of *M. wisconsensis* along with enterococci in approximately equal numbers from a swab of his gallbladder (Wittke et al., 1985). A definite pathogenic role for *M. wisconsensis* could not be established. Although unproven, it is likely that *M. wisconsensis* can cause disease in susceptible hosts in a fashion similar to that recorded for other rarely encountered genera of Enterobacteriaceae listed in this chapter.

The type strain of *M. wisconsensis* is CDC 2896-78 (= ATCC 35017).

Obesumbacterium

The genus has a checkered taxonomic history dating back to 1936 when it was first isolated from top-fermentation pitching-yeast samples associated with the brewing process (Shimwell, 1964). The genus is almost exclusively associated with breweries and the brewing process and most studies concerning *Obesumbacterium proteus* have been reported in brewery journals (Brenner, 1991). For a history of nomenclature and taxonomic changes associated with the genus *O. proteus*, please consult the extensive review of Farmer (1984).

In 1964, Shimwell proposed creation of a new genus, *Obesumbacterium*, to house short fat rods that were commonly found in breweries and had previously been designated “*Flavobacterium proteus*.” This proposal was based upon the facts that these organisms did not show any relationship to the genus “*Flavobacterium*” and did not fit into any other currently recognized genera. Thus, creation of a new genus was warranted and the name “*Obesumbacterium*” was proposed. Priest et al. (1973) demonstrated that *O. proteus* strains formed two phenotypic groups, both of which were compatible with inclusion in the family Enterobacteriaceae (Brenner, 1991). DNA hybridization studies, while not very discriminatory, indicated that that *O. proteus* was significantly related to the Enterobacteriaceae, and in particular to *Hafnia alvei* (Brenner, 1991). On the basis of these findings, Priest et al. (1973) proposed transferring *O. proteus* to *Hafnia*, as “*Hafnia protea*.” *Hafnia protea* was accepted and used by microbiologists in the brewery industry (Farmer, 1984). However, this name lost standing in nomenclature when it failed to appear on the *Approved Lists of Bacterial Names* (Skerman et al., 1980). *Obesumbacterium proteus* was on the *Approved List* and remains the accepted name (Brenner, 1991).

Brenner (1981) confirmed that *O. proteus* belonged in the Enterobacteriaceae and showed

Table 16. DNA relatedness of *O. proteus* biogroups.

^b*H. alvei* DNA hybridization groups cannot be unambiguously separated from one another biochemically.

Adapted from Brenner (1981, 1991) and Farmer (1999).

that the two biogroups were in fact separate species (Table 16).

Obesumbacterium proteus biogroup 1 is an anaerogenic biogroup of *H. alvei* DNA hybridization group 1 (Brenner, 1991). Biogroup 2 was related to *Escherichia blattae* (50–60% related at 60°C) and represents a new genomospecies within *Escherichia*. Unfortunately, the type strain of *O. proteus* (Priest 502 = CDC 4296-74 = NCIB 8771 = ACTT 12841) resides in *Obesumbacterium* biogroup 1 (Brenner, 1991), and therefore, by definition, is *H. alvei*, since *H. alvei* genomospecies 1 contains the type strain ATCC 13337 (= NCTC 8105 = CDC 434-68) of *H. alvei*. The type strain of *O. proteus* shares 99.5% 16S rDNA sequence similarity with *H. alvei* ATCC 13337 (Spröer et al., 1999). This means that there is no valid type strain for *O. proteus*. The high degree of DNA relatedness between *O. proteus* biogroup 2 and *E. blattae* brings into question the legitimacy of the genus *Obesumbacterium* and whether biogroup 2 should be transferred to the genus *Escherichia* (Brenner, 1991). The G+C content of *O. proteus* is 49 mol% (Priest et al., 1973). Both *O. proteus* biogroups produce ECA (Ramia et al., 1982).

Obesumbacterium proteus is a pleomorphic, nonmotile bacterium (0.8–2.0 µm in width and 1.5–100 µm in length), ranging in shape from short plump rods to long pleomorphic bacilli (Farmer, 1984). *Obesumbacterium* grows slowly with colonies <0.5 mm in size after overnight incubation on most common media (Farmer, 1984). *Obesumbacterium proteus* produces acid from the fermentation of D-glucose and D-mannose and is lysine decarboxylase-positive. Biogroup 1 differs from the two DNA relatedness groups of *H. alvei* in that it fails to produce gas from the fermentation D-glucose and does not ferment D-xylose (Brenner, 1991). As with both DNA hybridization groups of *H. alvei*, biogroup 1 of *O. proteus* is susceptible to the *Hafnia*-specific bacteriophage 1672 of Guinée and Valkenburg (1968). *Obesumbacterium proteus* biogroup 2 is easily separable from *H. alvei* and from *O. proteus* biogroup 1 by its lack of susceptibility to the *Hafnia*-specific bacteriophage, its inability to ferment D-mannitol, and its negative Voges-Proskauer reaction (Brenner, 1991). Salient biochemical features are listed in Table 17.

Obesumbacterium is exclusively isolated from breweries, beer wort, and the brewing fermenta-

tion process. There are no clinical isolates of *O. proteus*.

There is no valid type strain of *O. proteus* at present.

Pantoea

The genus *Pantoea* was created in 1989 by Gavini and colleagues to house two closely related taxa that had formerly resided in several genera, including *Enterobacter* and *Erwinia*. One taxon, referred to as “DNA hybridization group (HG) 27155” by Beji and others (Beji et al., 1988) consisted of the type strain of *Enterobacter agglomerans* (ATCC 27155) and strains belonging to the B4 phenom of Gavini et al. (1983a). An electrophoretic protein analysis of these strains indicated that those belonging to protein profile group 1, which correlated with phenoms 7B and 8 of Verdonck et al. (1987), were highly related at the DNA level with a minimum DNA relatedness of 81% (Beji et al., 1988). Several other protein groups (III–VI) were also demonstrated by DNA-DNA hybridization to be 82–96% related to ATCC 27155. Also, HG 27155 appeared identical to Brenner’s HG XIII since three HG XIII strains of Brenner were 94–95% related to ATCC 27155 (Brenner et al., 1984). Included within HG 27155 were the type strains of *E. agglomerans* (ATCC 27155), *Erwinia herbicola* (NCPPB 2971) and *Erwinia milletiae* (NCPPB 2519). The second taxon, referred to as “DNA HG 14589” consisted of five strains from Gavini’s B5 phenom, three strains from Verdonck’s phenom 10, CDC 1429-71 from Brenner’s HG III, and *Erwinia herbicola* ATCC 14589. The closest relative of HG 14589 was HG 27155, which exhibited 41–53% DNA relatedness as determined by DNA-DNA hybridization (Gavini et al., 1989). HG 14589 was only 28% related to the type strains of *Erwinia caratovora* and *Erwinia amylovora* and 1–37% related to 37 other genera and species in the family Enterobacteriaceae (Gavini et al., 1989). These data indicated that both HG 27155 and HG 14589 were discrete species in the family Enterobacteriaceae and should be placed in a separate genus. Gavini et al. (1989) proposed the genus *Pantoea* for these two taxa. The species name “*agglomerans*” has priority in the literature over the epithets *herbicola* and *milletiae* according to the *International Code of Nomenclature of Bacteria* edited by Sneath (1992). *Enterobacter agglomerans* (HG 27155) was therefore transferred to the new genus as *Pantoea agglomerans* (Gavini et al., 1989). HG 14589 was named *P. dispersa*.

A Japanese study of bacterial strains that produced 2,5-diketo-D-gluconic acid from D-glucose placed 42 of these isolates into the genus *Erwinia*

as “*Erwinia citreus*,” “*Erwinia punctata*” and “*Erwinia terreus*” (Kageyama et al., 1992). Subsequent numerical taxonomy studies performed on 37 of these isolates identified three phenoms represented by strains SHS 2003, SHS 2006 and SHS 2008. Using simple matching coefficients, these three phenoms displayed the greatest similarity (68.4%) to *P. agglomerans* and *P. dispersa*. Group SHS 2003 was 28–41% related to groups SHS 2006 and SHS 2008 by DNA-DNA hybridization (S1 nuclease, 60°C). Group SHS 2006 was 38–46% related to group SHS 2008. Interspecies relatedness of four SHS 2006 strains and four SHS 2008 strains was 85–100% and 71–99%, respectively (Kageyama et al., 1992). The DNA relatedness of each of these groups to other strains of the *Erwinia herbicola-Enterobacter agglomerans* complex, other *Erwinia* and *Enterobacter* species, and selected genera in the family Enterobacteriaceae was <20%. Relatedness to *P. agglomerans* and *P. dispersa* was 9–18%. Based primarily on phenotypic relatedness and numerical taxonomy studies, which produced a closest match with the genus *Pantoea*, Kageyama et al. (1992) proposed the names “*P. citrea*,” “*P. punctata*” and “*P. terrea*” for groups represented by strains SHS 2003, SHS 2006 and SHS 2008, respectively. Two additional DNA HGs were subsequently detected by Mergaert et al. (1993). HG 2665 contained the type strains for *Erwinia ananas* and *Erwinia ure-dovora* plus five other *Erwinia* strains representative of protein profile groups I to V. The interspecies relatedness of these 7 strains was 76–100% as determined by DNA-DNA hybridization (renaturation measured spectrophotometrically, 74°C). Mergaert et al. (1993) proposed that HG 2665 be transferred to the genus *Pantoea* as *P. ananas*, since the epithet *ananas* has priority in the literature over *ure-dovora*. A second HG, which consisted of six *Erwinia* isolates, including three *E. stewartii* strains, represented protein profile groups VI–IX. Two subgroups existed within this HG-labeled subgroup, 2632 and 2715. Subgroup 2715 contained the type strain of *Erwinia stewartii*. Intergroup relatedness was >93%. Subgroups 2632 and 2715 were 60–83% related to each other, but only 30–39% related to *E. ananas* (HG 2665). Based on these DNA relatedness values, the second HG was transferred to the genus *Pantoea* as *P. stewartii* with subgroup 2715 as *P. stewartii* subsp. *stewartii* and 2632 as *P. stewartii* subsp. *indologenes* (Mergaert et al., 1993).

In a phylogenetic study of 29 plant-associated strains based upon 16S rDNA sequences, four *Pantoea* species, including the type strains of *P. ananas* and *P. stewartii* formed a monophyletic unit (cluster IV), closely related to *Erwinia* (Hauben et al., 1998). The 16S rDNA sequence

similarities for these four strains ranged from 95.9 to 98.8% with an average similarity of 96.1% with *Erwinia* species. The G+C content of the genus *Pantoea* was originally reported as 55.1–60.6 mol% (Gavini et al., 1989); however, the G+C content for *P. punctata*, *P. citrea* and *P. terrea* is 50–50.3, 49.7 and 51.0–51.9 mol%, respectively (Kageyama et al., 1992), which has led to an amended description of the genus *Pantoea* (Mergaert et al., 1993). *Pantoea agglomerans*, *P. ananas* and *P. stewartii* express ECA (Böttger et al., 1987).

Members of the genus *Pantoea* are widely distributed in nature occurring in many different ecologic habitats, including in association with plants, soil, water, as well as with humans and other animals (Gavini et al., 1989). Plant surfaces, seeds, water, clinical samples, animals, and raw and frozen vegetables harbor *P. agglomerans* (Gavini et al., 1989; Iimura and Hosono, 1996; Österblad et al., 1999). *Pantoea dispersa* has been recovered from plant surfaces, seeds and humans (Gavini et al., 1989). *Pantoea citrea*, *P. punctata* and *P. terrea* have been isolated from Japanese fruit, particularly mandarin oranges (Kageyama et al., 1992); *P. terrea* has also been isolated from soil. *Pantoea ananas* has been isolated from pineapple, rice seeds, and from the wheat fungal pathogen *Puccinia graminis* (Mergaert et al., 1993). *Pantoea stewartii* has been isolated from grasses, pineapple and beetles.

Members of the genus *Pantoea* share most of the classic phenotypic characteristics associated with genera in the family Enterobacteriaceae. For most *Pantoea* species, good growth occurs over a temperature range of 20–36°C. Almost 90% of *P. ananas* strains grow at 4°C, but not most other *Pantoea* species with the exception of *P. stewartii* subsp. *indologenes* (Mergaert et al.,

1993). In contrast, *P. dispersa* grows at 41°C, while most other *Pantoea* species do not (Gavini et al., 1989). *Pantoea citrea*, *P. punctata* and *P. terrea* grow at a pH range of 6.0–7.5 and all three require nicotinamide or nicotinic acid for growth (Kageyama et al., 1992). Biochemically, all *Pantoea* species are negative for lysine and ornithine decarboxylase and arginine dihydrolase. Thus, they need to be separated from other H₂S-negative genera in the Enterobacteriaceae (see Table 10). Although *Pantoea* species are H₂S-negative on traditional media such as triple-sugar, iron-agar slants, *P. citrea*, *P. punctata* and *P. terrea* are H₂S-positive in cysteine-based media (Kageyama et al., 1992). Salient phenotypic tests useful in determining the species designation of individual *Pantoea* isolates are provided in Table 18.

Pantoea species are primarily plant pathogens. *Pantoea agglomerans* has been associated with the gall formation on *Wisteria* species and on Baby's breath (*Gypsophila paniculata*). It has also been implicated in stalk and leaf necrosis of onions (Gavini et al., 1989). On the leaves of beach peas (*Lathyrus maritimus*), it causes black spot necrosis (Khetmalas et al., 1996). *Pantoea dispersa* has been associated with leaf spot in okra (*Abelmoschus esculentus*). *Pantoea citrea* appears to cause pink disease of pineapples (Pujol and Kado, 2000). The disease is characterized by a distinct orange-brown color produced in fruit tissue after the heating process of canning. Discoloration appears to be due to production of 2, 5-diketogluconate by *P. citrea*. *Pantoea stewartii* subsp. *stewartii* causes the vascular disease Stewart's bacterial wilt of corn (*Zea mays*). *Pantoea stewartii* subsp. *indologenes* causes leaf spot in foxtail and pearl millet (Mergaert et al., 1993). It also causes pineapple rot (*Ananas comosus*).

<i>P. stewartii</i>	LMG 2715	NCPBP 2295; ATCC 8199; ICMP 257; DSM 30176; ICPB SS11; IMET 11187

Because of the confusing taxonomy and the difficulty in identifying *Pantoea* isolates to species, little is presently known about their relative pathogenicity in humans, although it is assumed to be low. *Pantoea agglomerans* has been isolated from leg wounds, a knee exudate, sputum, trachea, spinal fluid, urine, conjunctiva and peritoneal dialysis fluid (Janda and Abbott, 1998). The older literature contains numerous reports of the recovery of “*Enterobacter agglomerans*” linked to outbreaks of pseudobacteremia associated with contaminated medical devices or solutions (Astagneau et al., 1994). “*Enterobacter agglomerans*” has also been linked to “cotton fever,” an acute febrile condition associated with postinjection of intravenous heroin in narcotic abusers using cotton as a filter for heroin (Ferguson et al., 1993). De Champs et al. (2000) have recently described two cases of septic monoarthritis caused by *P. agglomerans* after penetrating injuries caused by a thorn and a wood sliver. The role other *Pantoea* species in human disease is presently unknown.

The type strains of *Pantoea* species are listed in Table 19.

Pectobacterium

The genus *Pectobacterium* was revived by Hauben et al. in 1998 during a study of phytopathogenic strains belonging to the family Enterobacteriaceae (Hauben et al., 1998). In that investigation, the phylogenetic position of these isolates was assessed using almost complete 16S rDNA sequences for 29 plant-associated strains. Construction of a neighbor-joining dendrogram identified one cluster (Cluster II) consisting of five subspecies of *Erwinia caratovora*, *E. cacti-cida*, *E. chrysanthemi* and *E. cyripedii*. The mean 16S rDNA sequence similarity value for these eight strains was 96.8%. The sequence similarity of this cluster to the genera *Erwinia*, *Brenneria* and *Pantoea* ranged from 95.3 to 95.6%. Sequence divergence within the subspecies of *E. caratovora* varied from 1.2 to 3.0%. Strains of *E. caratovorum*, *E. chrysanthemi* and *E. cyripedii* had previously been shown to be only 16–22%

related to *E. amylovora* by DNA binding (Brenner et al., 1974). Cluster II exhibited only 95.6% similarity to true erwinias, while *Pantoea* (cluster IV) demonstrated only an average of 96.1% 16S rDNA sequence similarity with *Erwinia*. Based upon this latter fact, Hauben et al. (1998) proposed that cluster II should be considered a distinct genus and supported the revival of the genus *Pectobacterium*, which originally included pectinolytic Enterobacteriaceae (Waldee, 1945). *Pectobacterium* contains signature nucleotides G, C, T, T, G, C, A, A, C, G, C, C, T, A, G, T, T and A at sequence positions 408, 434, 594, 598, 599, 638, 639, 646, 839, 847, 848, 988, 989, 1216, 1217, 1218, 1308 and 1329 according to the *E. coli* 16S rRNA gene sequence (Hauben et al., 1998). Spröer et al. (1999) has subsequently conducted phylogenetic studies on 15 genera within the family Enterobacteriaceae, including three species of *Pectobacterium*. In contrast to both Kwon et al. (1997) and Hauben et al. (1998), these authors did not find that *Pectobacterium* formed a phylogenetically well separated cluster, but rather depicted the origin of *Brenneria* species within the radiation of *Pectobacterium* species (Spröer et al., 1999). The suggestion that the genus *Pectobacterium* is composed of a polyphyletic group is supported by nucleotide sequence studies on a 447-bp segment of the *gapDH* locus, which encodes for the glyceraldehyde-3-phosphate dehydrogenase (Brown et al., 2000). Studies of *gapDH* sequence evolution indicate that *P. chrysanthemi* and *P. cacti-cida* have evolved separately from the *P. caratovorum* clade. The differences in conclusions need to be addressed. The G+C content for *Pectobacterium* species is 50.5–54.6 mol% (Hauben et al., 1998). *Pectobacterium caratovorum* and *P. cyripedii* produce the ECA, while *P. chrysanthemi* does not (Böttger et al., 1987).

Pectobacterium species were formerly classified in the “caratovora” group of the genus *Erwinia*. With the exception of *P. cyripedii*, *Pectobacterium* species produce strong pectinolytic activity and cause soft rot, necrosis, and wilts on crops and ornamental plants (Hauben et al., 1998). These species cause soft rot in a wide range of vegetables and plants including pota-

toes, carrots, onions, sugarbeets, sweet potatoes, papayas and cabbage (Sinha and Prasad, 1977; Hauben et al., 1998).

The genus *Pectobacterium* possesses the defining phenotypic features of the family Enterobacteriaceae. All species are negative for lysine-, ornithine decarboxylase and arginine dihydrolase, and thus, must be separated from phenotypically similar genera, including *Erwinia*, *Brenneria*, *Pantoea* and other unusual genera in the family Enterobacteriaceae (see Table 10). They fail to deaminate tryptophan and are urea-negative but hydrolyze esculin. Additional biochemical features of the genus *Pectobacterium* can be found in Hauben et al. (1998). Key differential traits useful in identifying *Pectobacterium* isolates to species level are listed in Table 20.

Pectobacterium species cause a variety of plant diseases. Various subspecies of *P. carotovorum* causes storage rot in potato tubers, vascular necroses in roots of sugarbeets, rotting diseases on Japanese horseradish, and slimy rot of witloof chicory (Hauben et al., 1998). *Pectobacterium chrysanthemi* causes vascular wilts or parenchymal necroses in corn and other food crops (Hauben et al., 1998). *Pectobacterium cacticidum* is found in soft rot tissues of cacti (Alcorn et al., 1991). *Pectobacterium cyripedii* causes brown rot in orchids (Hauben et al., 1998).

The type strains of *Pectobacterium* species are listed in Table 21.

Photorhabdus

The genus *Photorhabdus* was proposed in 1993 to include bacterial endosymbionts of entomopathogenic nematodes that had previously

been assigned to the genus *Xenorhabdus* as *X. luminescens* (Boemare et al., 1993). Creation of this new genus appeared warranted since *X. luminescens* strains were significantly different from all other known *Xenorhabdus* strains at that time on a genetic, phenotypic, physiologic and ecologic basis (Boemare et al., 1993). DNA relatedness studies conducted by Grimont et al. (1984) demonstrated only low intraspecies DNA relatedness values between *X. nematophilus* and *X. luminescens* (8–12%, S1 nuclease method; 17–37%, hydroxyapatite method). Subsequent studies using the hydroxyapatite method confirmed these earlier observations. The DNA of *X. luminescens* strains was found to have relative binding ratios of only 5–23% to other nonluminescent members of *Xenorhabdus* (Boemare et al., 1993). RNase T1-resistant oligonucleotide 16S rRNA cataloguing of *X. luminescens* ATCC 29999 and ATCC 29304 yielded a similarity coefficient of 0.71 to *X. nematophilus* ATCC 19061, indicating only moderate relatedness between these two species (Ehlers and Stackebrandt, 1988). These two groups are further distinguished by the presence in *X. luminescens* of more branched chain fatty acids (C₁₋₁₅, C₁₋₁₇) and a smaller percentage (<10%) of cyclopropane acid (C_{17-cy}; Janse and Smits, 1990; Suzuki et al., 1990). In addition to genetic investigations, *X. luminescens* is catalase-positive and bioluminescent, while all other *Xenorhabdus* strains are catalase-negative and nonluminescent. Furthermore, bioluminescent bacteria are known to be endosymbionts of the family Heterorhabditidae, while other nonluminescent members of the genus *Xenorhabdus* are primarily associated with nematodes of the family Steinernematidae (Akhurst et al., 1996). Based upon this collective

data, Boemare et al. (1993) transferred *X. luminescens* to a new genus, *Photorhabdus*. The genus name, which means “light rod” is reflective of the unique phenotypic attribute of this species.

Although the genus *Xenorhabdus* appears to be more diverse than the genus *Photorhabdus* (Fischer-Le Saux et al., 1998), early studies indicated that more than one DNA relatedness group existed within *P. luminescens* (Grimont et al., 1984). DNA relatedness studies (hydroxyapatite method) conducted on 31 *P. luminescens* strains found two distinct DNA groups, one composed of symbiont strains and one composed of clinical isolates (Akhurst et al., 1996). A polyphasic taxonomic survey employing DNA pairing (S1 method) studies, 16S rRNA inferences, and phenotypic characteristics of 23 *Photorhabdus* strains further defined the genus (Fischer-Le Saux et al., 1999). Using a broader definition of a species (60–80% relatedness, ΔT_m between 5°C and 7°C divergence), Fischer-Le Saux et al. (1999) proposed the creation of two new nomenclatures. One species, designated “*P. asymbiotica*,” contained clinical isolates of *P. luminescens* previously recognized as a unique taxon by Akhurst and colleagues (Akhurst et al., 1996). The second new species, *P. temperata*, consisted of seven endosymbiotic strains isolated from *Heterorhabditis bacteriophora*, *Heterorhabditis megidis* or *Heterorhabditis zealandica*. Both *P. luminescens* and *P. temperata* could be further divided into subspecies, with strains in each subgroup exhibiting >80% relatedness with ΔT_m of <1.5°C (Fischer-Le Saux et al., 1999); however, there are many taxonomic issues regarding *Photorhabdus*. The type strain (Hb) for *Photorhabdus* appears to be an atypical representative of the genus, since only one other strain belonging to the same taxa (*P. luminescens* subsp. *luminescens*) has been identified. Also the number of *Photorhabdus* strains isolated from diverse hosts needs to be expanded to better understand the genetic diversity and phylogenetic depth of the genus. Recent DNA relatedness studies clearly indicate that there are strains with unique 16S rDNA genotypes that do not reside within any current recognized *Photorhabdus* nomenclatures based upon DNA-DNA pairing studies (Fischer-Le Saux et al., 1998; Fischer-Le Saux et al., 1999). Finally, whether a relaxed species concept as proposed by Fischer-Le Saux et al. (1999) to delineate taxa within the genus *Photorhabdus* is relevant remains to be determined.

Photorhabdus is a member of the γ subdivision of the class Proteobacteria (Ehlers et al., 1988). Phylogenetic trees constructed using 16S rDNA sequence data places *Proteus vulgaris* and *Arsenophonus nasoniae* as its nearest neighbors exhibiting 93.5–95.1% sequence similarity (Rainey et al., 1995; Suzuki et al., 1996; Liu et al.

1997; Szállás et al., 1997; Spröer et al., 1999). The phylogenetic positioning of the genus next to *Proteus*, however, indicates that *Photorhabdus* is not an ancient (“core”) member of this family. Another association linking *Photorhabdus* with the family Enterobacteriaceae is the fact that *P. luminescens* ATCC 29999 and ATCC 29304 contain the 16S rRNA signature sequence CAAC-CCUUAUCCUUUG, which is only found in enterobacteria (Ehlers et al., 1988). *Xenorhabdus* species can be distinguished from *Photorhabdus* by the occurrence of a signature nucleotide sequence between positions 208 and 211 (*E. coli* numbering) of 16S rDNA (Szállás et al., 1997). *Photorhabdus luminescens* expresses the ECA (Ramia et al., 1982; Böttger et al., 1987). The G+C content of the genus is 43–44 mol% (Boemare et al., 1993).

Photorhabdus does not apparently exist in a free-living form in the environment since genetically marked strains of *Photorhabdus* released into river water or soil samples fail to survive for more than 7 days (Morgan et al., 1997). Rather *Photorhabdus* species appear to coexist in nature in an intimate symbiotic association with entomopathogenic nematodes of the family Heterorhabditidae. *Photorhabdus* bacteria live throughout the intestine of infective juvenile nematodes (third-instar, L3 stage, dauer larva) that are present in soil waiting to prey on their next insect host (Forst et al., 1997). Nematodes entering the larval stage of a variety of insects eventually penetrate into the hemocoel of the host, acting as a “living syringe” by releasing symbiotic bacteria into the hemolymph (Forst et al., 1997; Fischer-Le Saux et al., 1998). Acting in concert, bacteria and nematodes then kill insect larva with *Photorhabdus* species playing a major pathogenic role. Within the hemocoel of the larval carcass, nematodes reproduce sexually and bacteria grow to stationary phase (Forst et al., 1997). The nematode provides protection and transport for the bacterial endosymbionts in soil and in the insect host (Liu et al., 1997; Fischer-Le Saux et al., 1999). In return, bacteria symbionts provide nutrients for nematodes and release antimicrobial substances that suppress contamination of the cadaver by other microorganisms, thereby facilitating their sexual reproduction in the insect carcass (Forst and Neilson, 1996). Prior to release from this carcass, bacteria reassociate with nematodes that are then released as infective juveniles ready to seek a new host as the life cycle repeats itself. Up to 0.5 million infective nematodes per gram of host are released from the cadaver two or more weeks after death (Boemare and Akhurst, 1988).

An additional characteristic of the life cycle in entomopathogenic nematodes of *Photorhabdus* spp. is phase variation. Bacterial cells recovered

Table 22. Distinguishing features of phase I and II cells of *Photorhabdus* spp.

Trait	Phase I	Phase II

From Boemare and Akhurst (1988), Boemare et al. (1993), Akhurst et al. (1996), and Forst et al. (1997).

from infective juvenile nematodes are termed “phase I cells” or “primary form symbionts.” Upon in vitro cultivation or when directly isolated from clinical material, phase I cells convert to or exist as a more stable form called “phase II (secondary) cells” (Farmer et al., 1989; Forst et al., 1997). A number of phenetic differences exist between both phase variants and are listed in Table 22.

In addition to the properties described in Table 22, a number of other structural or phenotypic features distinguish phase I and II cells (reviewed in Forst et al., 1997). DNA pairing studies, however, clearly demonstrate that both phases are 100% related to each other in reciprocal hybridization experiments or in their relative binding ratios to *P. luminescens* Hb^T (Boemare et al., 1993; Akhurst et al., 1996). Some intermediate-type colonies have been described that possess one or more phase I characteristics (Boemare et al., 1993).

The genus *Photorhabdus* consists of Gram-negative pleomorphic rods that range in size from 2 to 10 µm by 0.5 to 2.0 µm depending upon the age of the culture and phase of the isolate (see above); filaments as long as 30 µm can occur (Boemare et al., 1993). Bacteria are motile via peritrichous flagellation. Many strains produce red, pink or yellow colonies on enriched media, although this is not an invariable characteristic (Boemare and Akhurst, 1988; Boemare et al., 1993; Peel et al., 1999). Cardinal features of *Photorhabdus* species useful in separating them from other Enterobacteriaceae include bioluminescence, a negative nitrate reductase reaction, and an unusual type of hemolysis (Fischer-Le Saux et al., 1999; Peel et al., 1999). This last attribute, which occurs on sheep blood agar, was originally described by Farmer and colleagues (Farmer et al., 1989) and consists of no hemolysis immediately surrounding the colony but rather a thin line (~2 mm) of hemolysis about 13 mm from the edge. This type of hemolysis is now referred to as “annular hemolysis” (Fischer-Le Saux et al., 1999). Consistent biochemical features of the genus include negative reactions for lysine and ornithine decarboxylase, arginine dihydrolase,

and ONPG (*o*-nitrophenyl-β-galactopyranoside) activity. Few carbohydrates are fermented with the exception of D-glucose, fructose and D-mannose. *Photorhabdus* species need to be separated from other H₂S-negative genera expressing similar phenotypic traits (see Table 10). Comprehensive studies of the antimicrobial susceptibility profiles of clinical isolates of *Photorhabdus* (*P. asymbiotica*) have not been undertaken. From individual reports it appears that most strains are susceptible in vitro to the aminoglycosides, tetracycline, naldixic acid and third-generation cephalosporins, while often resistant to ampicillin, cephalothin and penicillin (Farmer et al., 1989; Peel et al., 1999). In vitro susceptibility results may not, however, always correlate with clinical response (Peel et al., 1999).

Biochemical tests useful in the identification of *Photorhabdus* spp. are listed in Table 23.

At present, the identification of *Photorhabdus* species can be fraught with many difficulties. Two genomospecies, *P. luminescens* and *P. temperata*, each contain one or more strains that do not taxonomically reside within described subspecies (Fischer-Le Saux et al., 1999). These strains often have phenotypic properties that are different from those described for named subspecies within each taxa. Farmer et al. (1989) have also indicated that the inactivity of *P. asymbiotica*

strains (formerly *X. luminescens* DNA hybridization group 5) may cause problems for clinical laboratories in regards to their recognition and identification.

The bioluminescence genes have been cloned from several strains of *P. luminescens* (strains Hm, Hb and HW) and expressed in *E. coli*. The organization of these strains is similar to those in other bioluminescent species with the luciferase genes (*luxA* and *luxB*) flanked by genes encoding for enzymes of the fatty acid reductase complex (Frackman et al., 1990). The order of genes in strain HW is CDABE (Xi et al., 1991). Probes constructed to *luxA* and *luxB*, which encode for the α and β subunits of the luciferase gene, react in Southern blots against all *P. luminescens* strains including primary and secondary forms (Frackman et al., 1990). Under low stringency conditions, these probes also hybridize to other bioluminescent bacteria in the genera *Vibrio* and *Photobacterium*. The α and β subunits of the luciferase gene of strain HW exhibit 51–83% sequence identity to those of *V. harveyi*, *V. fischeri* and *P. leiognathi* and 84–93% sequence identity to the *luxA* and *luxB* genes of other *P. luminescens* strains (Xi et al., 1991). A number of genes associated with the toxin complex loci (*tc*) of *P. luminescens* have been cloned (ffrench-Constant and Bowen, 1999; Waterfield et al., 2001). These four loci (*tca*, *tcb*, *tcc* and *tcd*) appear to demonstrate little homology to previously identified bacterial toxins and no significant overall similarity to any sequences deposited in GenBank (ffrench-Constant and Bowen, 1999). Their precise composition and mode of action are unknown.

Because of their ability to kill a variety of insects ranging from cockroaches to boll weevils, *Photorhabdus* species are viewed as potentially important bacteria useful in insect pest control (Forst et al., 1997). The use of *Photorhabdus* in insect pest control may have important advantages over other entomopathogenic bacteria such as *Bacillus thuringiensis* since the former species may have an expanded host range and may produce new pesticidal toxins to which insects have not acquired resistance. A toxin complex (*tc*) locus in *P. luminescens* encodes for four toxin complexes designated “Tca,” “Tcb,” “Tcc” and “Tcd” (Waterfield et al., 2001). The exact composition and function of these high molecular weight insecticidal toxin complexes is presently unknown, although a number of ORFs found around the *tc* complex exhibit similarity to *E. coli* colicins and *Pseudomonas aeruginosa* pyocin (Waterfield et al., 2001). In addition to their pathogenic role in insects, two recent reports have described the isolation of *Photorhabdus* strains from human infections (Farmer et al., 1989; Peel et al., 1999). Farmer and others

Table 24. Type strains of *Photorhabdus* species.

Species	Type strain	Other designations
<i>P. luminescens</i>	Hb	ATCC 29999; DSM 3368; NCIB 12670
<i>P. temperata</i>	X1Nach	CIP 105563
<i>P. asymbiotica</i>	CDC 3265-86	ATCC 43950

(Farmer et al., 1989) reported on six isolates (including one case in the addendum) of *Xenorhabdus luminescens* (now *P. asymbiotica*) that had been recovered from clinical specimens including wounds and blood. Although the medical history on three of these cases was fragmentary, there was compelling evidence in two instances (one involving a wound infection of the lower leg in a 45-year-old man) that *Photorhabdus* was indeed a human pathogen. A second case involved a 78-year-old man with a pretibial wound infection, which implicated *Photorhabdus* as a copathogen with *Staphylococcus aureus*. A decade later, Peel et al. (1999) described four additional illnesses linked to *Photorhabdus luminescens* infection. Three of these four illnesses involved middle-aged to elderly persons with multiple cutaneous lesions (one with a positive blood culture) that primarily affected the limbs. A fourth patient, a 90-year-old male, apparently developed *Photorhabdus* bacteremia of unknown etiology. One striking finding from both studies was a clinical history documenting a spider bite in two cases and a suggested bite in a third that preceded development of *Photorhabdus* wound infections. This indicates arachnids may be potential vehicles of *Photorhabdus* infections.

The type strains of *Photorhabdus* species are listed in Table 24.

Pragia

Pragia fontium is the only species in the genus *Pragia* (Aldová et al., 1988; Brenner, 1991). Bouvet et al. (1985) first showed *P. fontium* was a different species than *B. aquatica* (both species are H₂S-positive and are isolated from water). The 18 known *Pragia* strains were all isolated in Czechoslovakia, 17 from well water or water pipes and one from the stool of a healthy woman (Aldová et al., 1988; Brenner, 1991). Phylogenetic analysis of the type strain of *P. fontium* indicates that *Pragia* forms a distinct lineage in the family, well separated from other Enterobacteriaceae genera (Spröer et al., 1999).

Pragia fontium usually gives – + – + IMViC reactions, is H₂S-positive, motile, and LDC-, ODC-, and ADH-negative (Brenner, 1991). It ferments very few sugars other than D-glucose

and D-galactose and does not grow at 42°C. Oxidation of gluconate by *P. fontium* helps to separate *Pragia* from *Budvicia* and other H₂S-producing genera in the family Enterobacteriaceae (Aldová et al., 1988). Additional characteristics useful in separating H₂S-positive genera/species can be found in Table 4. Whole cell protein profiles can also be used to distinguish *Pragia* from phenotypically similar genera including *Budvicia* and *Leminorella* as strains of each group cluster together (Schindler et al., 1992). Some strains produce a *Shigella*-like odor on nutrient agar (Aldová et al., 1988). An isolation medium has been designed by Schubert and Groeger-Söhn (1998) for the recovery of *P. fontium* from surface waters. This medium differs from that described for *B. aquatica* (see *Budvicia*) only in the concentration of cephalothin (15.0 µg/ml) added to the basal medium.

Seven strains of *P. fontium* were 85–94% related to the type strain (CNCTC Eb11/82) at both 60°C and 75°C using the hydroxapatite method. Among members of the Enterobacteriaceae, *P. fontium* was most closely related to *B. aquatica* (37%) but was 17% or less related to all other members of this family. The G+C content is 46–47 mol% (Aldová et al., 1988). *Pragia fontium* produces the ECA (Böttger et al., 1987).

The type strain of *P. fontium* is CNCTC Eb11/82 (= ATCC 49100 = CCUG 18073 = CDC 963-84 = DRL 20125 = IP 20125).

Rahnella

Gavini et al. (1976), during a study of the genus *Enterobacter*, used the name “Group H₂” for phenotypically similar, phenylalanine deaminase-positive strains that may have been included in the *Enterobacter agglomerans*-*Erwinia herbicola* complex on the basis of their negative lysine- and ornithine decarboxylase reactions, and negative arginine dihydrolase reaction (Brenner, 1991). On the basis of DNA relatedness reactions on 12 of the 20 strains of Group H₂, a single species, *Rahnella aquatilis*, was proposed in the new genus *Rahnella* (Izard et al., 1979). Relatedness values to the labeled type strain were 57–98% with four of the 11 strains tested giving values below the 70% usually considered to reflect species-level relatedness (Brenner, 1991). Recent investigations employing a polyphasic taxonomic approach have identified at least three genomospecies within *Rahnella aquatilis* (Brenner et al., 1998). Genomospecies 1 includes the type strain of *Rahnella aquatilis* and 17 other strains. The mean DNA interspecies relatedness of genomospecies 1 strains (*R. aquatilis sensu stricto*) was 88% at

60°C (range 72–100%) with a mean divergence of 3.5% (range 0–7%). Genomospecies 2 consisted of 30 strains primarily from contaminated blood, snails and water. Interspecies relatedness was 93% (range 73–100%) with a mean sequence divergence of 1.5% (range 0.5–5.5%) in 60°C reactions. The final DNA group consists of a single strain (DSM 30078) from an unknown source. The type strain of *R. aquatilis* (CCUG 14185) was 70% related with 8% divergence to genomospecies 2 in 60°C reactions and 50% related in 75°C reactions. CCUG 14185 was 64% related with 9% divergence in 60°C reactions to DSM 30078 (Brenner et al., 1998). The reference strain for genomospecies 2 was 56% related with 8% divergence to strains belonging to *R. aquatilis* (genomospecies 1). Because genomospecies 2 and 3 could not be unambiguously separated phenotypically from *R. aquatilis sensu stricto*, they were left unnamed and the vernacular names “*Rahnella* genomospecies 2 and 3” were proposed (Brenner et al., 1998). Detailed phylogenetic investigations on the genus *Rahnella* have not been undertaken; however, two independent studies that have constructed dendrograms of the major members of the family Enterobacteriaceae using 16S rDNA data have identified *E. americana* as the closest neighbor of *R. aquatilis* (Hauben et al., 1998; Spröer et al., 1999). The G+C content of *R. aquatilis* and related organisms is 51–56 mol% (Izard et al., 1979; Brenner, 1991). *Rahnella aquatilis* produces the ECA (Böttger et al., 1987).

Rahnella is widely distributed in nature with water being the major reservoir for these microorganisms (Farmer et al., 1985). *Rahnella aquatilis* has also been recovered from a variety of other environmental niches, including soil, the rhizosphere of wheat and maize, from fermenting wort, and from fresh Italian ryegrass (Berge et al., 1991; Hamze et al., 1991; Heron et al., 1993). It has even been recently identified from the intestinal contents of a 12,000-year-old mastodon (*Mammuth americanum*) using 16S ribosomal (rDNA) sequencing (Rhodes et al., 1998). Many food products also contain *R. aquatilis* such as vegetables (Österblad et al., 1999). A Swedish study of minced meat, retail fish, and pasteurized milk and cream yielded both *R. aquatilis* and *Hafnia alvei* in high numbers (>10⁶ cfu/g) in all three products (Lindberg et al., 1998). In addition to environmental foci, *R. aquatilis* has been recovered from human blood, urine and respiratory secretions (Oh and Tay, 1995).

Rahnella aquatilis is a nonpigmented bacillus that is motile at 25°C, but not at 36°C (Brenner, 1991). Strains of *Rahnella aquatilis* deaminate phenylalanine, but the reaction is weaker than seen in *Proteus* and *Providencia* (Farmer et al.,

1985). The ONPG reaction is positive. *Rahnella aquatilis* is reported to be negative for H₂S, lysine and ornithine decarboxylase, and arginine dihydrolase by Farmer et al. (1985) and later Brenner et al. (1998) and thus must be separated from phenotypically similar organisms (see Table 10). However, the original description states that the arginine dihydrolase reaction is variable, with most strains positive (Izard et al., 1979). Variation in ornithine decarboxylase reactions has also been reported by different laboratories (Brenner et al., 1998). Most *Rahnella* and *Rahnella*-like strains ferment L-arabinose, D-glucose, lactose, D-mannitol, salicin, cellobiose, maltose, D-mannose, melibiose, L-rhamnose and sucrose (Brenner et al., 1998). Genomespecies 1 (*R. aquatilis sensu stricto*) and genomespecies 2 cannot be unambiguously differentiated using phenotypic methods, although utilization of L-histidine, L-ornithine, L-proline and hydrolysis of *para*-nitrophenyl- β -D-glucopyranoside and L-proline-*para*-nitroanilide are useful in distinguishing these two genomespecies (Brenner et al., 1998). Most *R. aquatilis* and *R. aquatilis*-like strains are resistant to aminopenicillins (e.g., ampicillin and amoxacillin), first generation cephalosporins and cephamycins (Funke and Rosner, 1995; Stock et al., 2000). Resistance to second-generation cephalosporins, such as cefuroxime, has also been noted.

Rahnella aquatilis is an uncommon human pathogen. Most human infections have involved episodes of bacteremia in men (less commonly in women) that are either immunocompromised or have other serious underlying illnesses (Oh and Tay, 1995; Reina and Lopez, 1996); however, cases of *R. aquatilis* sepsis in immunocompetent adults have been described (Chang et al., 1999). Nosocomial transmission of *R. aquatilis* has also been documented on one occasion (Caroff et al., 1998). Other *R. aquatilis*-related diseases include urinary tract infections, postsurgical wound infections, and endocarditis (Alballaa et al., 1992; Maraki et al., 1994; Matsukura et al., 1996). Although the sources for most human illnesses remain unknown, both Hickman catheters and contaminated parenteral nutrition have been implicated as vehicles of infection (Oh and Tay, 1995; Caroff et al., 1998). In one instance, *R. aquatilis* sepsis resulted from a contaminated (1000-ml bottle of) 5% dextrose-vitamin B complex-vitamin C solution bought over-the-counter by a 26-year-old Korean man who was subsequently infused by an unlicensed individual (Chang et al., 1999). Most strains are susceptible to the aminoglycosides, third generation cephalosporins, quinolones, carbapenems, monobactams, tetracyclines and sulfa-containing compounds (Funke and Rosner, 1995; Caroff et al., 1998; Stock et al., 2000).

The type strain of *R. aquatilis* is 133 (= CIP 78-65 = ATCC 33071).

Raoultella

Drancourt et al. (2001) have proposed the transfer of three *Klebsiella* species to a new genus, *Raoultella*, based upon phylogenetic analyses of 16S rDNA and *rpoB* (bacterial RNA polymerase β -subunit) genes. Using neighbor-joining and maximum-parsimony methods, three clusters within *Klebsiella* were evident with cluster II containing *K. ornithinolytica*, *K. terrigena* and *K. planticola*. These three species share several phenotypic traits in common with each other including growth at 10°C and utilization of L-sorbose as a carbon source. Using 98% 16S rDNA and 94% *rpoB* sequence similarity as breakpoints for delineating different genera, the proposal to transfer these three species to the genus *Raoultella* was made (Drancourt et al., 2001); however, these three species do not form as tight a phyletic line as cluster I, which contains the three subspecies of *K. pneumoniae* with 98.2–99.7% 16S rDNA sequence similarity and 99.4–100% *rpoB* sequence similarity, respectively. Additionally, the placement of *K. terrigena* in this genus is questionable and further DNA pairing studies seem warranted.

Sodalis

Members of the genus *Sodalis* are secondary (S) endosymbionts of the tsetse fly, *Glossina morsitans morsitans*, and reside in multiple host tissues, including midgut epithelial cells (Dale and Maudlin, 1999). Infection of insect cells in vitro appears to be facilitated through *Sodalis* genes that encode for components of a type III secretory system, which include a gene with a high sequence identity to *invC* (Dale et al., 2001b). Previous studies on S endosymbionts have demonstrated they are members of the γ -3 subclass of the class Proteobacteria and form a distinct lineage within the family Enterobacteriaceae (Aksoy et al., 1995b; Dale and Maudlin, 1999). In 1999, Dale and Maudlin were able to successfully isolate and grow an axenic culture (strain M1) of an S endosymbiont from a previously infected insect cell line of *Aedes albopictus* inoculated with hemolymph from a laboratory colony of tsetse flies. Based upon phylogenetic analysis of these organisms and unique phenotypic properties associated with agar-grown bacteria, the name “*Sodalis glossinidius*” was proposed to include S-endosymbionts found in *G. morsitans morsitans* and *G. pallidipes* (Dale and Maudlin, 1999).

Sodalis appears to be vertically transmitted through maternal milk glands (Cheng and Aksoy, 1999). Eradication of S-endosymbionts (*S. glossinidius*) from tsetse flies with streptozotocin has little effect upon fly reproductivity but does reduce longevity (Dale and Welburn, 2001a). Eradication also increases the refractory nature of tsetse flies to parasitism by trypanosomes. This suggests S-endosymbionts might serve as important delivery systems for anti-parasite gene expression (Dale and Maudlin, 1999). *Sodalis glossinidius* can either be cultured using mosquito (*Aedes albopictus*) feeder cell culture systems or can be grown in vitro on Mitsuhashi-Maramorosch (MM) agar supplemented with fresh horse blood or catalase (Dale and Maudlin, 1999). Optimal growth occurs under microaerophilic conditions (<10% oxygen) at 25°C; no growth occurs at temperatures exceeding 30°C. Colonial morphology is pleomorphic and not maintained upon subculture. Cells are nonmotile, filamentous, Gram-negative rods, 2–12 µm in length and 1–1.5 µm in diameter (Dale and Maudlin, 1999). *Sodalis glossinidius* is catalase-negative, an unusual trait for members of the family Enterobacteriaceae. Metabolically, *Sodalis* is very inactive with few carbohydrates fermented or assimilated. Exceptions to this rule include D-glucose, D-mannitol, sorbitol, raffinose, N-acetyl-D-glucosamine, and glycol chitosan (Dale and Maudlin, 1999). *Sodalis glossinidius* produces at least one type of chitinase (Dale and Maudlin, 1999; Dale and Welburn, 2001a).

The type strain of *S. glossinidius* is M1 (= NCIMB 13495).

Tatumella

Tatumella ptyseos, the only species in *Tatumella*, was proposed by Hollis et al. (1981) for strains formerly called “EF-9” (eugonic fermenter; eugonic means rapid and relatively luxuriant growth). DNA relatedness of 25 strains to the type strain was 80–100% at an optimal reassociation temperature and 68–100% at a stringent reassociation temperature (Hollis et al., 1981; Brenner, 1991). Divergence within related sequences was 0.5% or less for 19 strains, but was 5.5–8.0% for 6 others (Brenner, 1991). Such high divergence values are extremely unusual within strains of a species; however, since these strains exhibited species-level relatedness to the type strain (as high as 88%) and were biochemically typical, they were included in the species. *Tatumella ptyseos* was less than 40% related to other Enterobacteriaceae and was 2% related to the type strain of *Chromobacterium violaceum* (Brenner, 1991). Phylogenetic analysis of the

type strain of *T. ptyseos* indicates that *Tatumella* forms a distinct lineage in the family well separated from other Enterobacteriaceae genera (Spröer et al., 1999). The G+C content of *T. ptyseos* is 53–54 mol%. Diaminopropane and putrescine are the major polyamines produced (Hamana, 1996). *Tatumella ptyseos* produces ECA (Ramia et al., 1982).

Over fifty *T. ptyseos* strains are now in the CDC collection (Farmer et al., 1985). Forty-six of these are from the respiratory tract (mainly sputum), which is reflected in the species name *ptyseos*, which means “a spitting.” Three isolates are from blood. *Tatumella ptyseos* has additionally been recovered from the blood of a Malaysian neonate with jaundice and presumed sepsis (Tan et al., 1989). She was treated with ampicillin and gentamicin and recovered uneventfully.

Tatumella ptyseos is an H₂S-negative species that is lysine and ornithine decarboxylase- and arginine dihydrolase-negative. Thus, it must be separated from phenotypically similar genera in the Enterobacteriaceae (Table 10). It is also indole- and Voges-Proskauer-negative and ferments few carbohydrates other than D-glucose, sucrose, trehalose and salicin (some strains). *Tatumella ptyseos* is quite atypical for Enterobacteriaceae in several phenotypic characteristics (Brenner, 1991). It is generally more active at 25°C and is nonmotile at 36°C. Two-thirds of strains are motile at 25°C. Flagella are difficult to demonstrate, and when present, are polar, subpolar, or lateral—not peritrichous as in all other motile members of the family (Hollis et al., 1981; Brenner, 1991). Strains are susceptible to penicillin. All strains grow on MacConkey and other plating media commonly used for Enterobacteriaceae (Brenner, 1991). Survival on commonly used agars or semisolid stock culture media is not always good, and *T. ptyseos* does not survive for a week on blood agar. It is recommended that the organism be held frozen at –40°C or colder in 5% defibrinated rabbit blood for long-term storage, although this process may not ensure preservation of all strains (Hollis et al., 1981).

The type strain of *T. ptyseos* is D16168 (= CDC 9591-78 = ATCC 33301 = DSM 5000).

Trabulsiella

The genus *Trabulsiella* consists of a single species, *T. guamensis*, previously referred to by the vernacular name “CDC Enteric Group 90” (McWhorter et al., 1991). Seven strains were found to be 98–100% related to the type strain at 60°C and 94–100% related at 75°C. The type strain of *T. guamensis* was 6–41% related to 62 other strains from other Enterobacteriaceae spe-

cies. The highest relatedness values obtained from DNA pairing studies were with *Salmonella* and *Kluyvera ascorbata* (McWhorter et al., 1991).

In the original description of the genus, McWhorter et al. (1991) described eight strains, six of which were isolated from vacuum cleaner dust in Guam. The remaining *T. guamensis* strains originated from human stool specimens from Germany and New York. An addendum to this article reported on four additional strains. Three of these strains were from environmental sources (one from wheat flour and two were unspecified) and a fourth strain was from the feces of a 44-year-old German man with a fever of unknown origin (McWhorter et al., 1991). There is no evidence presently that *T. guamensis* causes disease in humans.

Strains of *Trabulsiella* were originally recognized because of their biochemical similarity to *Salmonella* subgroups 4 and 5, although the former group failed to agglutinate in *Salmonella* O and H typing sera (McWhorter et al., 1991). *Trabulsiella guamensis* is a motile, oxidase-negative, facultatively anaerobic Gram-negative rod that produces H₂S on triple sugar iron and peptone iron agar slants (Table 4). It produces both lysine and ornithine decarboxylase within 24 hours; 50% of strains also produce arginine dihydrolase within 48 hours. *Trabulsiella* is indole- and Voges-Proskauer-negative, ONPG- and mucate-positive, and produces acid from the fermentation of a large number of carbohydrates including D-glucose, L-arabinose, cellobiose, D-mannitol, L-rhamnose and D-sorbitol. There appear to be at least two biogroups of *T. guamensis*. Biogroup 1 strains are indole-positive, and hydrolyze gelatin (film method) and esculin. Biogroup 2 strains are negative for these traits. An unusual biochemical property of the genus is the ability to hydrolyze tyrosine crystals (McWhorter et al., 1991). *Trabulsiella guamensis* is susceptible to gentamicin, chloramphenicol, sulfamethoxazole, naladixic acid and resistant to penicillin, ampicillin and cephalothin by disk diffusion (McWhorter et al., 1991).

The type strain of *T. guamensis* is CDC 0370-85 (= ATCC 49490 = CIP 103637).

Wigglesworthia

The genus *Wigglesworthia* consists of a single species, *W. glossinidia*, that is a primary (P) endosymbiont of tsetse flies belonging to species and subspecies of the genus *Glossina* (Aksoy, 1995a). Unlike S endosymbionts (see *Sodalis*), *W. glossinidia* resides in specialized cells called “mycetocytes” that are located in the anterior region of the gut. These specialized cells form a white

U-shaped organelle called a “mycetome” (Aksoy, 1995a). *Wigglesworthia glossinidia* contains only a single operon encoding for 16S rDNA sequences. Phylogenetic analysis of 16S rDNA and ribosomal DNA internal transcribed spacer-2 (ITS-2) from P endosymbionts indicates that *Wigglesworthia* forms a distinct lineage in the γ subdivision of the Proteobacteria and exhibits concordant evolution with its insect host (Aksoy et al., 1997; Chen et al., 1999). Based upon 16S rDNA data, *W. glossinidia* is most closely related to the genus *Buchnera*, to S-endosymbionts of other insects, and to *Escherichia coli* (Aksoy, 1995a).

The exact mechanism by which maternal transmission of *Wigglesworthia* occurs is presently unknown (Aksoy et al., 1997). Eradication of P endosymbionts through treatment of tsetse flies with ampicillin and tetracycline results in a greater than 50% reduction in fecundity and pupal emergence, which essentially leads to insect sterility (Dale and Welburn, 2001a).

Wigglesworthia glossinidia cannot be grown outside the insect host, although it can be metabolically maintained active under transient tissue culture conditions for 72 hours or more (Aksoy, 1995a). Bacterial cells within mycetomes are rod-shaped and 4–5 μ m in length.

There is no type strain for *Wigglesworthia*. The genus and species were proposed on the basis of Rule 16a of the *International Code of Nomenclature of Bacteria* (Aksoy, 1995a).

Xenorhabdus

In 1965, Poinar and Thomas proposed the name “*Achromobacter nematophilus*” for the symbiotic organism found in the digestive tract of the nematode *Steinernema* (formerly *Neoaplectana*) *feltiae*. The genus name was subsequently rejected, resulting in a lengthy chronology of taxonomic proposals naming the bacterial symbiont and its nematode host (for a review, see Forst and Neilson, 1996). In 1979, Thomas and Poinar proposed the new genus *Xenorhabdus* in the family Enterobacteriaceae for the nematode symbiotic bacteria (Brenner, 1991). The genus was originally composed of two species, which included the type species, *X. nematophilus*, and the bioluminescent organism *X. luminescens*. The later species was subsequently transferred to the genus *Photorhabdus* as *P. luminescens* (Boemare et al., 1993; see *Photorhabdus*).

Akhurst (1983) proposed three subspecies of *X. nematophilus* on the basis of nematode host, pigment, maximum growth temperature, and biochemical tests (Brenner, 1991). These subspecies were designated “*X. nematophilus* subsp. *nematophilus*”, “*X. nematophilus* subsp. *bovie-*

nii” and “*X. nematophilus* subsp. *poinarii*.” He later described a fourth subspecies, “*X. nematophilus* subsp. *beddingii*,” for strains symbiotic with two undescribed *Steinernema* species (Brenner, 1991). Akhurst and Boemare (1988) proposed elevating of all of these subspecies to species status based upon numerical taxonomy studies involving 60 variable characters associated with *Xenorhabdus* subspecies and their associations with specific nematode hosts. Boemare et al. (1993) subsequently studied a broad sample of *Xenorhabdus* isolates by DNA hybridization. Using the hydroxyapatite method, *P. (“Xenorhabdus”) luminescens* was found to be only 4–11% related to other *Xenorhabdus* species (see *Photorhabdus*) and 0–15% related to 73 species of Enterobacteriaceae (Grimont et al., 1984; Boemare et al., 1993). Interspecies relatedness for *Xenorhabdus* (other than *P. luminescens*) was greater than 63%, while intraspecies relatedness ranged from 17 to 38%. These results confirm the validity of the proposed *Xenorhabdus* species as suggested by Akhurst and Boemare (1988). A fifth symbiont species, *X. japonicus*, associated with the nematode *Steinernema kushidai*, was described by Nishimura et al. (1994). The type strain (SK-1) was 29–51% related to other *Xenorhabdus* species in DNA–DNA hybridization assays.

Xenorhabdus is a member of the γ subdivision of the class Proteobacteria and forms a distinct side branch from core genera of the family Enterobacteriaceae (Ehlers et al., 1988; Stackebrandt et al., 1988). Binary similarity coefficients (0.65–0.69) of rRNA catalogues link the Enterobacteriaceae as nearest neighbors to *Xenorhabdus* and *Photorhabdus* when compared to the Aeromonadaceae (0.58), *Pasteurella* (0.53), vibrios and other marine organisms (0.35–0.55). They also contain several signature oligonucleotides present in all members of the family Enterobacteriaceae (Ehlers et al., 1988). On the intragenic level, *Xenorhabdus* species exhibit 97.2% 16S rDNA similarity and 92.7–96.1% similarity to other Enterobacteriaceae (Suzuki et al., 1996). Other groups of this subclass are less closely related with similarity values of less than 90% (Rainey et al., 1995). *Xenorhabdus* strains can be clearly distinguished from *P. luminescens* by a signature UUCG sequence present in the former genus between positions 208 to 211, while the latter group contains a longer UGAAAG version (Sz  ll  s et al., 1997); however, some controversy still exists regarding whether *Xenorhabdus* (as well as *Photorhabdus*) should be placed in this family (Forst and Neilson, 1996). This point of view is supported by fatty acid analyses and the fact that *Xenorhabdus* is unable to reduce nitrates and is catalase-negative, defining traits of this family. Equally controversial is the

phylogenetic position of both *Xenorhabdus* and *Photorhabdus*. While some distance matrices support the separate status of both entomopathogenic genera (Sz  ll  s et al., 1997; Forst et al., 1997), other 16S rDNA sequencing studies do not unambiguously come to the same conclusion (Rainey et al., 1995; Suzuki et al., 1996; Liu et al., 1997). The G+C content of *Xenorhabdus* is reportedly 43–50 mol% (Brenner, 1991). *Xenorhabdus nematophilus* produces the ECA (Ramia et al., 1982; B  ttger et al., 1987).

Xenorhabdus is carried monoxenically in the intestine of juvenile, free-living, nonfeeding nematodes that are insect pathogens, or entomopathogens (Brenner, 1991). *Xenorhabdus nematophilus* contains several ORFs with extensive homology to the *tc* genes of *Photorhabdus*, suggesting that these sequences may have similar insecticidal activity to those found in *P. luminescens* (French-Constant and Brown, 1999). However, *X. poinarii* is not pathogenic for common wax moth larvae (*Galleria mellonella*) and *X. japonicus* is not pathogenic for tobacco cutworm larvae (*Spodoptera litura*). Like *Photorhabdus*, *Xenorhabdus* species are symbionts of entomopathogenic nematodes, can be grown as free-living organisms in vitro, and display phenotypic variant forms (Forst and Neilson, 1996; Forst et al., 1997); however, they differ in several key aspects from one another, including nematode hosts (Table 25). Additional distinguishing characteristics can be found in the review of Forst and Neilson (1996).

Xenorhabdus has not been isolated in free-living form from soil or water and does not survive for more than 7 days in soil or water when introduced under experimental conditions (Morgan et al., 1997). This suggests that they require a symbiotic existence to survive in nature.

Xenorhabdus grows poorly and sometimes not at all at 36  C (Brenner, 1991). *Xenorhabdus* species do not reduce nitrates and are catalase-negative, reactions that are atypical for most members of the family Enterobacteriaceae (Brenner, 1991). They produce two colony forms, designated “phase I” and “phase II,” which are

Table 25. Selected distinguishing features of *Xenorhabdus* and *Photorhabdus*.

Character	<i>Xenorhabdus</i>	<i>Photorhabdus</i>

Table 27. Type strains of *Xenorhabdus* species.

Species	Type strain	Other designations
<i>X. beddingii</i>	Q58	UQM 2871 (colony form 1); UQM 2872 (colony form 2); DSM 4764
<i>X. bovienii</i>	T228	UQM 2210 [ATCC 35271] (colony form 1); UQM 2211 [ATCC 49109] (colony form 2)
<i>X. japonicus</i>	SK-1	IAM 14265
<i>X. nematophilus</i>	ATCC 19061	
<i>X. poinarii</i>	G1	ATCC 35272; UQM 2216; DSM 4768

found in infective juveniles and as stable in vitro forms, respectively. These two phases exhibit similar enzymatic and antimicrobial activities to those found in *P. luminescens* with the exception that lipase activity is stronger in phase II cells and weaker in phase I variant forms (Forst and Neilson, 1996). Tests of value in differentiating *Xenorhabdus* species are shown in Table 26 (Brenner, 1991).

The type strains of *Xenorhabdus* species are listed in Table 27.

Yokenella (*Koserella*)

In 1985, Hickman-Brenner et al. proposed the name “*Koserella trabulsii*” for a biochemical and phylogenetically new taxa that had been previously referred to by a number of vernacular names including “*Hafnia* species 3” and “CDC Enteric Group 45” (Farmer et al., 1985; Brenner, 1991). Kosako et al. (1984) independently concluded that a group of strains resembling *H. alvei*, called “NIH (Japan) biogroup 9,” was a single DNA relatedness group that they named “*Yokenella regensburgei*.” These two groups were subsequently found to be identical in a collaborative study (Kosako et al., 1987) and because *K. trabulsii* is a junior subjective synonym (published later) of *Y. regensburgei*, the latter has priority (standing) in nomenclature (Kosako and Sakazaki, 1991). For a more detailed description of the taxonomic contro-

versy surrounding *Yokenella* and *Koserella*, consult the review of Brenner (1991).

The NIH (Japan) and CDC collections contained 23 *Y. regensburgei* stains, 16 of which were isolated from humans in the United States and Japan (Brenner, 1991). Eight of these isolates were from wounds, three each from urine and sputum, one from stool, and one from an unknown source. Six strains were isolated from insect intestines collected in Germany and one from well water in the United States (Brenner, 1991). The role of this bacterium in human disease is unknown. However, two cases of possible *Y. regensburgei* infection have been described. One involved a wound isolate associated with a septic knee process in a 74-year-old man, while the other was a case of transient bacteremia in a 35-year-old woman with liver disease. These cases suggest that *Y. regensburgei* may have a limited pathogenicity in immunocompromised persons (Abbott and Janda, 1994).

Yokenella regensburgei has a – + – + IMViC pattern. It is positive for lysine and ornithine decarboxylase and most strains fail to produce arginine dihydrolase activity (Abbott and Janda, 1994; Farmer, 1999). *Yokenella regensburgei* tests negative for H₂S production, urea, and phenylalanine deaminase (Brenner, 1991). Acid is produced from the fermentation of many carbohydrates including D-glucose, L-arabinose, cellobiose, D-mannitol, melibiose, L-rhamnose and D-xylose (Farmer, 1999).

The type strain of *Y. regensburgei* is NIH 725-83 (= JCM 2403).

Phylogenetic Relationships of Bacteria with Special Reference to Endosymbionts and Enteric Species

M. PILAR FRANCINO, SCOTT R. SANTOS AND HOWARD OCHMAN

Introduction

The latter half of the 20th century saw two developments that revolutionized the study of bacterial systematics and our conceptions about microbial diversity. The first was the use of molecular genetic information, as gained through the analysis of protein and nucleic acid sequences, for the identification, typing and classification of microorganisms. The second was the application of the polymerase chain reaction (PCR) for the recovery of DNA sequences from noncultivable organisms.

By decoupling cultivation and classification, and by providing a common yardstick by which all organisms could be compared (i.e., small subunit ribosomal DNA sequences; hereafter referred to as “SSU rRNA”), these procedures added a new dimension to our knowledge of the microbial world. It is no longer necessary to test organisms against a panel of known phenotypic or biochemical properties, which, in themselves, are often variable in occurrence and can lead to cases of misclassification, or carry a preconceived notion about the characters that define a particular taxonomic group.

Despite the considerable advances made from applying these innovations, such an approach is not without its limitations. Characterization of a single conserved sequence, while often adequate for taxonomic purposes, does not reveal very much about the evolutionary history or biology of the organism *per se*. Whereas the placement of an organism (i.e., sequence) into an evolutionary framework may prompt numerous predictions about its morphology, ecology, physiology and biochemistry, virtually nothing can be said about its unique biology without cultivation or additional sequence information.

Other problems can arise when attempting to classify bacteria and to determine their relationships. These derive from two sources: the specific characters used to represent an organism (the choice of data) and the algorithms used to infer relationships (the methods used to construct the phylogeny or tree). With this in mind, genotypic

data hold several advantages over phenotypic characters for phylogenetic reconstruction in that: 1) variation in molecular sequences is discrete and well-defined; 2) molecular sequences comprise hundreds, if not thousands, of characters bearing potentially useful information; 3) molecular sequences accumulate informative changes, even when the resulting phenotypes are conserved; 4) informational macromolecules (DNA and proteins) change according to well-defined models of sequence evolution; and 5) identical phenotypes can arise by very different genetic mechanisms or pathways, such that changes other than those attributable to common ancestry can lead to the same phenotype.

Questions of character convergence are not limited to phenotypic traits: portions of molecular sequences may be identical owing to chance, natural selection, or lateral gene transfer. Furthermore, because the analysis of relatively small regions of DNA can furnish so much information, phylogenetic relationships are often based on data collected from a very limited portion of the genome, which may or may not be representative of the organism as a whole. Such problems stress the need to examine multiple genes and to infer statistically robust phylogenetic trees, which assists in recognizing inconsistencies in the data and in establishing an evolutionary framework for studying the biology of an organism.

A Genomic View of Bacterial Evolution

The first goal of this chapter is to examine how information coming from completely sequenced microbial genomes has contributed to our interpretations of bacterial phylogeny and evolution. The molecular evolutionary history of microbes has largely been based on the evaluation of SSU rRNA (Fox et al., 1977; Fox et al., 1980; Woese, 1987; Hugenholtz et al., 1998; Maidak et al., 2000); however, the analysis of several conserved protein-coding regions has offered alternative scenarios relating to the branching orders of bac-

terial taxa, the rooting of the universal tree of life, and the role of lateral transfer in the early evolution and formation of genomes (Gogarten et al., 1989; Iwabe et al., 1989; Hilario and Gogarten, 1993; Brown and Doolittle, 1995; Golding and Gupta, 1995; Baldauf et al., 1996; Eisen, 1998; Forterre and Phillipe, 1999; Schutz et al., 2000). Such results have promoted the view that SSU rRNA might not fully reveal the relationships among organisms because genomes contain genes from multiple sources. Quite apart from the fact that SSU rRNA spans a very small portion and may not be representative of an entire genome, other concerns have been raised about the use of this molecule as the sole basis for molecular phylogenetic reconstructions. The size of SSU rRNA (ca.1600 nucleotides) and its very slow rate of evolution contribute to the fact that there are often too few variable sites to resolve phylogenetic relationships accurately. Furthermore, because rRNA does not encode a protein, the occurrence of frequent additions and deletions in certain portions of the molecule presents problems for sequence alignments, and selection of secondary structures can cause sequence convergence and saturation (homoplasy), thereby distorting the actual relationships among organisms (Hillis and Dixon, 1991; Kjer, 1995; Huynen et al., 1997).

Complete genomes allow immediate access to the full set of sequences that are conserved among diverse genomes, which has greatly facilitated the analysis of genes other than those encoding SSU rRNA. Perhaps a hundred genes are conserved among all bacterial lineages, affording the opportunity to trace the evolutionary history of sequences representing a substantial fraction of the genome. Furthermore, the availability of complete genome sequences has led to the development of numerous “whole-genome” approaches for evaluating the relationships among organisms. These studies are certainly among the most interesting endeavors in the analysis of bacterial genomes and have broadened the scope of evolutionary studies to include new levels of genetic organization.

The second portion in this chapter concerns the phylogenetic relationships among microorganisms classified as Enterobacteriaceae. Considering that this family of bacteria includes the workhorses of molecular, genetic, and biochemical analyses (*Escherichia coli* and *Salmonella*) and contains pathogens causing diseases with substantial impact on human populations (plague, typhoid and dysentery), there is perhaps more known about the biology of these microbes than for any other group of organisms. As in many other taxa, there has been a shift towards the use of molecular characters to infer the relationships among enterics; however, phenotypic

markers still form much of the basis for typing the majority of strains, particularly in clinical settings. Because most enteric species were originally differentiated on the basis of biotyping rather than on genotypic characters, several of the current designations are arbitrary and do not reflect either the extent of genetic diversity or the true relationships among strains.

As an example, the Shigellae have traditionally been subdivided into four species—*Shigella boydii*, *S. flexneri*, *S. dysenteriae* and *S. sonnei*—although the total amount of genetic variation within this genus is fully contained within *E. coli*. Therefore, *Shigella* should not be classified as a genus separate from *Escherichia*. Furthermore, the amount of genetic diversity varies widely among the four *Shigella* species: *S. sonnei* constitutes a single genetically uniform lineage, whereas each of the other three species comprises a very heterogeneous array of clones. Finally, the classification of *Shigella* strains does not reflect their genetic similarities: strains of *S. flexneri* can be more closely related to *S. boydii* than to any other strains typed as *S. flexneri*, and both *Shigella boydii* and *S. dysenteriae* have multiple independent (polyphyletic) origins from within *E. coli*. Clearly, the Shigellae warrant reclassification based on genetic criteria, although the epidemiological consequences of a taxonomic revision are uncertain.

Although there are numerous cases where traditional classification is at odds with information from molecular sequences, or where the phylogenetic relationships based on different molecular characters are in conflict, our purpose in this chapter is not to amend or revise the taxonomic nomenclature either of the Enterobacteriaceae or of the major phyla of bacteria. Rather, we outline the rationale of the phylogenetic approach as it applies to bacteria, describe several of the molecular characters and methods used to infer phylogenetic trees, and review the phylogenetic relationships of strains derived from these procedures. Hopefully, in doing so, we have accomplished our ultimate goal, which is to provide an evolutionary framework for understanding the remarkable diversity of bacteria.

Bacterial Relationships and Realities

The living world is organized taxonomically into three domains—Archaea, Bacteria and Eucarya—which have been delineated in terms of their SSU rRNA sequences and cell membrane structures (Woese et al., 1990; Winker and Woese, 1991). Despite the prevailing nomenclature, Bacteria are the most ancient and are estimated to have appeared between 3.5 and 4

billion years ago. Bacteria comprise about 40 phyla (i.e., deep-branching subdivisions), about one-third of which presently contain representatives among the fully sequenced genomes. Naturally, cultivable, pathogenic, and small-genome bacteria have been the focus of most sequencing endeavors; however, substantial efforts are being made to expand both the phylogenetic and ecological scope of the set of sequenced microbes.

For assessing the broad-scale evolutionary relationships among the Bacteria, this chapter considers primarily those microbes for which full genome sequences are available. Although this limitation overlooks large portions of the genomic diversity within the Bacteria, it is useful to note that: 1) many recognized bacterial phyla are represented by only one or a few organisms for which we have little more than SSU rRNA sequences; and 2) the early radiation of the Bacteria into phyla occurred relatively rapidly, such that the set of sequenced organisms probably encompasses the range of variation within this domain.

The field of phylogenetics is constantly being challenged with new types of data, larger samples of organisms, and alternative models of evolution, and thus relies upon the continuous development of new methods to estimate, infer, test and resolve the relationships among organisms. Virtually all phylogenetic trees encountered in the literature are based on one of the following methods: 1) "Parsimony" finds the tree that requires the minimum number of changes; 2) "simple distance" generates the tree that best represents the matrix of pairwise distances between organisms; 3) "neighbor joining" is a distance method that progressively clusters pairs of taxa that yield the shortest total branch length; 4) "maximum likelihood" uncovers the tree that best fits a specified probabilistic model of sequence evolution; and 5) "Bayesian inference" relies upon the posterior probabilities of a tree to test the hypothesis that the particular topology is correct. Because the parsimony and likelihood methods compare all possible trees to find the optimal branching order, both become computationally intensive with increasing sample sizes. "Bootstrapping" is a data re-sampling procedure designed to test the degree of support for the branching order in a given tree, with numbers (bootstrap values) placed at nodes to indicate the percentage of replicates in which the same taxa are joined at a particular node.

Sequence-alignment-based Bacterial Phylogenies

Since the early 1980s, when small-scale DNA sequencing became affordable, bacterial phylo-

genetics has relied upon the comparison of homologous sequences in different taxa and in particular on SSU rRNA. Such comparisons have allowed for an ability to comprehend the diversity within the microbial world and to define major phylogenetic groups. The preponderance of SSU rRNA as a phylogenetic character stemmed mostly from the fact that it is universally distributed and slowly evolving, and performs essentially the same function in all life forms. However, ribosomal RNA is not unique in this respect in that many proteins have a very wide distribution, with over 100 protein-coding genes common to all Bacteria. Analyses based on different subsets of these shared genes, ranging from single genes to extensive sequence concatenations, have resulted in trees whose topologies differ in many respects from each other and from the SSU rRNA tree. The current challenges are: 1) to recognize among the wealth of sequence information available the subset of genes, or genomic characters, that carry the least distorted phylogenetic signal and 2) to develop methods that allow for the meaningful integration of information distilled from a wide number of genes.

The SSU rRNA Bacterial Phylogeny

The SSU rRNA tree for Bacteria currently delineates about 40 phyla, of which 13 are formed by uncultured species represented only by sequences directly cloned from the environment (Hugenholtz et al., 1998a; Hugenholtz et al., 1998b). However, the relationships among these phyla are very poorly resolved, so that, except for a few deep branching lineages, the SSU rRNA phylogeny resembles a bush rather than a tree, which is often interpreted as evidence for a rapid adaptive radiation and diversification of early bacterial life (Woese, 1987; Hugenholtz et al., 1998a; Hugenholtz et al., 1998b; Cavalier-Smith, 2002). Moreover, the addition of increasing numbers of taxa to the SSU rRNA tree has resulted in a failure to significantly support a single origin (i.e., monophyly) for some traditionally accepted phyla, such as the Proteobacteria. Indeed, although SSU rRNA clearly identifies a clade uniting the γ -, β - and α -Proteobacteria (with the first two as sister groups), it does not support the inclusion of the δ - and ϵ -Proteobacteria (Ludwig and Klenk, 2001). The best-supported, higher-level grouping in the SSU rRNA tree unites the phyla Chlorobi (green sulfur bacteria) and Bacteroidetes (Cytophaga/Flexibacter/Bacteroides group). Rooting of the tree with archaeal and eukaryotic sequences suggests that Aquificae is the most deeply branching bacterial phylum, followed by a number of phyla represented only by environmental sequences,

and by the *Thermodesulfobacteria*, the *Dictyoglomi* and the *Thermotogae*. All of these deeply branching phyla are thermophilic, which, along with the fact that thermophyly is thought to be ancestral in Archaea, has been taken as evidence for a “hot” origin of life (Pace, 1991). A reanalysis of SSU rRNA alignments restricted to slowly evolving positions, which are less prone to multiple substitutions and may be more reliable for early divergences (Brochier and Philippe, 2002a), groups *Aquificae* and *Thermotogae* in a derived position and places the phylum *Planctomycetes* as the basal lineage of the Bacteria.

Contrasting SSU rRNA Phylogeny with Other Phylogenetic Markers

Does the topology of the SSU rRNA tree reflect a true evolutionary explosion of phyla or does this topology result from a lack of resolving power of this molecule at this deep level? These questions have been addressed by the analysis of additional genes and proteins that are shared by all bacteria. Bacterial single-gene phylogenies have been produced for a considerable number of molecules, including large subunit (LSU; 23S) rRNA (De Rijk et al., 1995; Ludwig et al., 1998; Ludwig and Klenk, 2001), elongation factor EF-Tu (Ludwig et al., 1993; Delwiche et al., 1995; Baldauf et al., 1996; Gupta, 1998a; Ludwig et al., 1998; Bocchetta et al., 2000; Jenkins and Fuerst, 2001; Ludwig and Klenk, 2001), RNA polymerase (Klenk et al., 1999; Bocchetta et al., 2000) and sigma factor (Gruber and Bryant, 1997), RecA (Eisen, 1995; Gruber et al., 1998), cytochrome (Schutz et al., 2000) and ATPase subunits (Ludwig et al., 1993; Ludwig et al., 1998; Brown and Doolittle, 1997; Ludwig and Klenk, 2001), and heat shock proteins HSP60 (Viale et al., 1994) and HSP70 (Brown and Doolittle, 1997; Gupta et al., 1997b; Gupta et al., 1998). In general, no other single phylogenetic marker provides resolution much beyond the SSU rRNA tree. Most single-gene phylogenies support the existence of the phyla delineated by SSU rRNA, and in many cases, the basal placement of the hyperthermophilic phyla. Occasionally, single-gene phylogenies support the Chlorobi-Bacteroidetes relationship seen in the rRNA tree, or indicate novel clades, sometimes in contradiction with the rRNA phylogeny. The salient features of some of these trees are summarized below.

OTHER TRANSLATIONAL MOLECULES The phylogeny obtained with LSU rRNA is virtually identical to that of SSU (De Rijk et al., 1995; Ludwig et al., 1998; Ludwig and Klenk, 2001), which might be expected given the functional coupling of these molecules and their potential for being

affected by the same biases on sequence evolution (G+C pressure, selection on secondary structure, etc.). Although the LSU is longer and contains more potentially informative sites than the SSU, its resolution power at the level of inter-phylum relationships is equally poor; however, Brochier et al. (2002b) have analyzed a concatenated data set containing both rRNAs and obtained some interesting higher-level groupings. In this tree, which includes only species whose genomes have been sequenced, the ϵ -Proteobacteria are included along with the other proteobacterial classes with high bootstrap support (but the δ -Proteobacteria were not represented in the data set). Two clades strongly supported by the rRNA concatenation are that of Cyanobacteria and *Deinococcus* and that of the hyperthermophilic phyla *Aquificae* and *Thermotogae*, represented by the genome sequences of *Aquifex* and *Thermotoga*. In addition, in the concatenated rRNA tree, the hyperthermophiles are linked with the Actinobacteria. A close affiliation between *Thermotoga* and Gram-positive bacteria (Actinobacteria and Firmicutes) has been defended by Cavalier-Smith (Cavalier-Smith, 1992; Cavalier-Smith, 2002) on ultrastructural grounds and has been suggested by phylogenetic analyses based on different proteins (Tiboni et al., 1993; Brown et al., 1994; Karlin, 1995; Gupta, 1998a).

The translation elongation factor EF-Tu is, like rRNAs, a universally distributed component of the translation machinery, and highly conservative in sequence and function owing to its basic role in the elongation of nascent polypeptides. Many phylogenetic reconstructions have employed this marker and, overall, they are in good agreement with the rRNA trees (Ludwig et al., 1993; Delwiche et al., 1995; Baldauf et al., 1996; Gupta, 1998a; Ludwig et al., 1998; Bocchetta et al., 2000; Jenkins and Fuerst, 2001; Ludwig and Klenk, 2001). Unfortunately, the resolving power of EF-Tu is inferior to that of rRNA on account of the limited numbers of informative sites, and although it supports the clustering of Chlorobi and Bacteroidetes, it does not provide any further insight into inter-phyla relationships. Even a phylogeny based on a concatenation of EF-Tu and its paralog EF-G fails to recover the monophyly of Proteobacteria or any higher-level grouping, other than a clade uniting all phyla with the exception of the deeply branching *Deinococcus-Thermus*, *Thermotogae* and *Aquificae* (Bocchetta et al., 2000).

INFORMATION-PROCESSING PROTEINS Other well-conserved, information-processing molecules have been used for phylogenetic reconstruction, including RNA polymerase (Klenk et al., 1999; Bocchetta et al., 2000) and its σ^{70} -type sigma fac-

tor (Gruber and Bryant, 1997), and RecA (Eisen, 1995; Gruber et al., 1998). RNA polymerase (RNAP) presents the added advantage of being devoid of cases of paralogy, which often complicate protein-based phylogenies; however, the trees based on RNAP subunits are equivocal and differ from the rRNA tree in the position of the hyperthermophiles and the mycoplasmas. Instead of their commonly recovered placement at the base of the bacterial tree, Aquificae and Thermotogae branch in the proximity of Spirochaetes and Proteobacteria, while the mycoplasmas appear as the most divergent bacterial lineage. However, this result is likely an artifact resulting from the skewed base-composition and high rate of evolution of mycoplasmas because Aquificae and Thermotogae return to their usual position at the base of the tree when the mycoplasmas are removed from analysis (Bocchetta, 2000).

The phylogeny based on the σ^{70} -type sigma factor (a dissociable subunit of the RNA polymerase holoenzyme that confers promoter specificity) also displaces the Thermotogae from the base of the tree, grouping it with *Mycoplasma*, albeit with low support (Gruber and Bryant, 1997). In addition, this phylogeny strongly groups a monophyletic Proteobacteria (although the ϵ class is not represented) with Chlamydiae.

RecA is a versatile protein, involved in homologous DNA recombination and in the induction of the SOS response to DNA damage. The resolving power of RecA is higher than that of other proteins in that it recognizes the monophyly of Proteobacteria, although it cannot resolve the relative branching order of the δ and ϵ classes. The RecA-based phylogeny corroborates very strongly the relationship between Chlorobi and Bacteroidetes, as seen in rRNA and EF-Tu trees, but it does not provide any further insight into interphylum relationships (Eisen, 1995; Gruber et al., 1998).

PROTEINS INVOLVED IN METABOLISM AND OTHER CELLULAR PROCESSES

Numerous phylogenies have been obtained for molecules in noninformational roles, including the bioenergetics-related ATPases and cytochromes, and chaperonins. In the case of the ATPase β -subunit (Ludwig et al., 1993; Ludwig et al., 1998; Brown and Doolittle, 1997; Ludwig and Klenk, 2001), the resolving power of this protein is so low that monophyly is not recovered for such phyla as the Proteobacteria and the Firmicutes. On the other hand, a phylogeny based on subunits of cytochrome *bc* complexes contradicts the rRNA tree by grouping the Aquificae with the Proteobacteria (Schutz et al., 2000), as is also seen in some RNAP trees (Klenk et al., 1999; Bocchetta et al., 2000). Although the position of the Aquificae in

these trees may be due to homoplasy or horizontal transfer (Bocchetta et al., 2000; Schutz et al., 2000), other evidence hints to a relationship between the Aquificae and Proteobacteria. These two phyla share a long insertion in the RNAP β subunit not present in any other bacterial phylum (Klenk et al., 1999), as well as an insertion in alanyl-tRNA synthetase also seen in Chlamydiae, Chlorobi and Bacteroidetes (Gupta et al., 1999). These facts have led several authors to suggest that the Aquificae are in fact close relatives of Proteobacteria, and that their frequent position at the base of the bacterial tree is in reality an artifact caused by long-branch-attraction (Philippe and Laurent, 1998; Gupta et al., 1999; Cavalier-Smith, 2002).

The phylogenies based on the evolutionarily unrelated chaperonins HSP60 (or GroEL; Viale et al., 1994) and HSP70 (Brown and Doolittle, 1997; Gupta, 1998a; Gupta et al., 1997b) are specially interesting because they are the sole single-gene phylogenies that have been reported to divide relationships in the tight "bush"-like zone of the bacterial tree. HSP60 partitions the bacterial phyla into two well-separated clusters: 1) the Proteobacteria, Chlamydiae, Spirochaetes and Bacteroidetes, and 2) the Cyanobacteria, Actinobacteria and Firmicutes. In contrast, analyses by Gupta and coworkers (Gupta, 1998a; Gupta et al., 1997b) have found that chaperonin HSP70 includes the Cyanobacteria in cluster 1. In these phylogenies, the Deinococcus-Thermus phylum is strongly linked to Cyanobacteria, which results in a well-supported grouping of all Gram-negative phyla, and the two Gram-positive phyla (Actinobacteria and Firmicutes) are also united with relatively high support. However, archaeal genera also cluster with the Gram-positives, rendering the reliability of these HSP70-based phylogenies dubious. Moreover, a similar HSP70 analysis by Brown and Doolittle (1997) does not substantiate any significant high-level groupings among bacterial phyla.

Post-genomic Phylogenies Based on Alignments of Extensive Data Sets

Clearly, no single molecule possesses sufficient resolving power to clarify the ancient relationships among bacterial phyla. Moreover, the conflicts between phylogenies obtained with different markers and the growing awareness of the contribution of horizontal gene transfer to the bacterial genome indicate that phylogenies based on single molecules may not be representative of the evolution of organisms and have even cast doubts on the existence of an organismal bacterial phylogeny (Gogarten, 1995; Doolittle, 1999; Zhaxybayeva and Gogarten, 2002). The recent availability of genomic

sequences for numerous bacterial species has enabled the application of very large data sets to phylogeny reconstruction. In this section, we consider the bacterial phylogenies obtained through the analysis of extensive protein sequence alignments. Two main approaches have been applied to unify the information from different molecules into a single tree: 1) concatenation of sequences for the different molecules prior to phylogenetic analysis, or 2) separate phylogenetic analysis of each molecule and a posteriori coding of the information from individual phylogenies into a single “supertree.”

CONCATENATION-BASED ANALYSES In the concatenation approach, each of the molecules in the analysis must be present in all species considered. Therefore, attempts to reconstruct the phylogeny of bacteria through sequence concatenations have employed different subsets of widely distributed proteins. Brown et al. (2001) utilized proteins conserved across species from all domains (Archaea, Bacteria and Eucarya), from which they removed those proteins producing trees that intermixed species from different domains (which was interpreted as evidence of horizontal transfer). The remaining subset of universally distributed proteins contained 14 information-processing molecules, mostly involved in translation. Other studies have deliberately focused on extensive concatenations of translational proteins (Brochier et al., 2002b), and more specifically, of ribosomal proteins (Hansmann and Martin, 2000; Wolf et al., 2001; M. P. Francino, unpublished analysis). Proteins of the translational apparatus, particularly ribosomal proteins, have long been thought to be less prone to horizontal transfers owing to their high level of intermolecular interactions (viz., the “complexity” hypothesis; Jain et al., 1999). Although cases of horizontal transfer of translational molecules (Doolittle and Handy, 1998; Zhaxybayeva and Gogarten, 2002), including ribosomal proteins (Brochier et al., 2000; Makarova et al., 2001; Zhaxybayeva and Gogarten, 2002) and rRNA (Yap et al., 1999), have been reported, most of these proteins seem to produce phylogenies that are congruent among themselves and with the rRNA tree, suggesting that they belong to a core set of rarely transferred genes (Brochier et al., 2002b).

The phylogenies obtained in most concatenation-based analyses retrieve the monophyly of all established bacterial phyla. In the cases where Chlorobi and Bacteroidetes are represented, they are grouped together with very high bootstrap support (Brown et al., 2001; Brochier et al., 2002b). Remarkably, these phylogenies, although not identical, recover several of the same high-level clades. For example, Chlamydiae

and Spirochaetes group together in most concatenation-based analyses (Hansmann and Martin, 2000; Brown et al., 2001; Wolf et al., 2001; Brochier et al., 2002b), a relationship not detected in single-gene phylogenies. Similarly, Aquificae and Thermotogae are often grouped together, and occur at the base in rooted versions of the bacterial tree (Hansmann and Martin, 2000; Wolf et al., 2001; Brochier et al., 2002b; M. P. Francino, unpublished analysis), although not in the analysis by Brown et al. (2001) where they remain in their usual placement as basal but separate lineages.

Most interesting are groupings that involve deeper relationships between several phyla. A cluster retrieved in several studies is that of Actinobacteria, Deinococcus-Thermus and Cyanobacteria (Wolf et al., 2001; Brochier et al., 2002b; M. P. Francino, unpublished analysis), although the sister relationships within the group differ among analyses. Actinobacteria and Cyanobacteria cluster together in the work of Wolf et al. (2001), whereas *Deinococcus* clusters with Actinobacteria in the work of Brochier et al. (2002b) and with Cyanobacteria in a more recent analysis with a much wider representation of cyanobacterial species (M. P. Francino, unpublished analysis). In the work of Brown et al. (2001), *Deinococcus* also groups with Cyanobacteria, but the relative placement of this cluster is not resolved. In addition, in all three analyses (Wolf et al., 2001; Brochier et al., 2002b; M. P. Francino, unpublished analysis) the Actinobacteria, Deinococcus-Thermus and Cyanobacteria cluster at a deeper level with the Firmicutes. Finally, another well-supported deep branch separating two large assemblages of phyla is recovered in the analyses of Brochier et al. (2002b) and Francino (unpublished analysis). This branch separates Proteobacteria, Chlamydiae, Spirochaetes, Bacteroidetes and Chlorobi (not present in Francino’s analysis) from all other phyla. As mentioned, the HSP60 tree of Viale et al. (1994) also separates Proteobacteria, Chlamydiae, Spirochaetes and Bacteroidetes from the remaining represented phyla (Actinobacteria, Cyanobacteria and Firmicutes), and no large-scale, alignment-based phylogeny has a high level of support for any branch that would contradict this grouping.

SUPERTREE CONSTRUCTION In an alternative approach, Daubin et al. (Daubin et al., 2001; Daubin et al., 2002) propose the independent analysis of individual protein phylogenies, followed by coding of the information obtained from each phylogeny into a matrix that will be used to generate a “supertree”. This approach is less restrictive than sequence concatenation because it can incorporate phylogenies based on different subsamples of species, and therefore

can exploit the information contained in proteins that have limited distribution. In addition, the separate phylogenetic analysis of each protein alignment enables the use of specifically optimized sequence evolution models. Daubin et al. (2002) generated trees for 310 proteins present in at least 10 bacterial species with sequenced genomes, from which they retained a subset of 120 that supported similar phylogenies and were therefore judged to represent a common history, mostly devoid of horizontal transfer. For each protein tree, supported clades were encoded in a binary matrix, with weighting proportional to the bootstrap value, and the individual matrices were concatenated into a single matrix, which was used for maximum parsimony tree reconstruction (Baum, 1992; Ragan, 1992).

The supertree obtained recovers the monophyly of all established bacterial phyla, as well as some of the high-level clades supported by other analyses. As does the analysis of translational proteins by Brochier et al. (2002b), the supertree supports the clustering of *Deinococcus* and Actinobacteria. However, unlike the majority of concatenation-based studies, the supertree does not significantly support the grouping of Cyanobacteria with *Deinococcus* and Actinobacteria, or with any other phylum. The position of these phyla in the bacterial tree is therefore still controversial. Nevertheless, several arguments favor a grouping of *Deinococcus*-*Thermus* with Cyanobacteria. This cluster is recovered in the large-scale studies of Brown et al. (2001) and Francino (unpublished analysis) and in the analysis of a concatenation of SSU and LSU rRNAs by Brochier et al. (2002b). Moreover, this relationship is also supported by chaperonin HSP70 trees and by patterns of indels in several proteins (see Indel Signature Sequences); Gupta, 1998a; Gupta et al., 1997b; Gupta and Johari, 1998b). The clustering of *Deinococcus* with Actinobacteria in the supertree and in the analysis of translational proteins by Brochier et al. (2002b) may be an artifact due to shared GC-rich base composition. The initial placement of the *Deinococcus*-*Thermus* phylum after hyperthermophiles near the base of the bacterial tree is not supported by any large-scale alignment-based studies, nor by later versions of the SSU rRNA tree (Hugenholtz et al., 1998a; b).

The supertree strongly groups the phyla Aquificae and Thermotogae, but there is no support for them as the basal lineage of Bacteria. This result mirrors that of Brochier and Philippe (2002a) on the basis of slowly evolving rRNA positions and a well-sampled representation of bacterial species. The grouping of the hyperthermophiles, although observed in many recent analyses (Hansmann and Martin, 2000; Daubin et al., 2001; Daubin et al., 2002; Wolf et al., 2001;

Brochier and Philippe, 2002a; Brochier et al., 2002b; M. P. Francino, unpublished analysis), may result from biases in nucleotide and amino acid composition due to adaptation to high temperatures. Nevertheless, the recurrence of this grouping in large-scale analyses and the relatively frequent displacement of these phyla from the base of the bacterial tree (Gruber and Bryant, 1997; Klenk et al., 1999; Bocchetta et al., 2000; Schutz et al., 2000; Daubin et al., 2001; Daubin et al., 2002; Brochier and Philippe, 2002a) seriously challenge the long held view that thermophily is the ancestral state. Instead of the hyperthermophiles, the supertree favors the Spirochaetes and Chlamydiae as the most basal bacterial lineages. Unlike large-scale concatenation-based analyses (Hansmann and Martin, 2000; Brown et al., 2001; Wolf et al., 2001; Brochier et al., 2002b), the supertree does not group these two phyla together, but rather places them as separate lineages at the base of the bacterial tree. Other phyla have also been reported to occupy the most basal position in the bacterial tree, most notably the Planctomycetes, in the analysis of slowly evolving rRNA sites by Brochier and Philippe (2002a). Hence, the resolution of the rooting of the bacterial tree still requires a much broader sample of genomic sequences for the different candidate phyla.

INDEL SIGNATURE SEQUENCES In addition to traditional approaches based on the analysis of nucleotide or amino acid substitutions, large sets of protein alignments have also been inspected for insertions and deletions (indels) to be employed as markers for phylogenetic reconstruction. Certain protein sequences are polymorphic for indels, and the presence or absence of particular indels can be used to assort bacteria into groups. If identical insertion or deletion events do not arise independently in different lineages, these characters could also be used to infer the branching order and relationships among organisms. Gupta (Gupta, 2000; Gupta, 2001) has shown that the occurrence of specific indels defines most bacterial phyla as cohesive groups, and by tracing the distribution of numerous indels in different proteins, he has hypothesized an order of appearance for these phyla. Although the assignment of an ancestral state is not explicit in such reconstructions, the indel "signatures" place the Gram-positive bacteria as closely aligned with the Archaea—satisfying because both have a single-membrane cell wall producing a positive Gram stain—and invoke a single origin for all two-membrane bacteria.

In conclusion, large-scale alignment-based approaches are providing new insights into deep relationships between the bacterial phyla, but different analyses are generating conflicting

Fig. 1. Relationships among bacterial phyla most often represented in large-scale phylogenetic analyses. The cladogram depicts the basic topology of the small subunit (SSU) rRNA tree: Aquificae and Thermotogae are placed at the base, and all other phyla appear in a “bush”-like zone, where only a clade uniting Bacteroidetes and Chlorobi is resolved. Colored boxes indicate relationships strongly supported by other types of phylogenetic analyses, mostly based on protein sequence concatenations or whole-genome characters. The orange arrow indicates the proposed association between Aquificae and Proteobacteria. Purple arrows indicate alternative candidate phyla for the most basal position in the tree. The phylum Planctomycetes has no representatives for which a complete genome is available and has not been included in analyses based on extensive data sets. See text for references to the studies supporting each of the depicted relationships.

results, most notably regarding the placement of the root of the bacterial tree (Fig. 1). Although bacterial genome sequences are now appearing at a rapid rate, species sampling is still highly biased, mostly towards pathogenic and cultivable members of a restricted number of phyla. A further increase in resolution of bacterial relationships awaits a more widespread sampling of lineages. In addition, enhanced resolution will require the development of new methodologies that enable the optimal integration of information from large numbers of protein alignments. At present, the increased phylogenetic signal detected in large-scale analyses and the detection of a core of genes that have undergone similar histories (Brochier et al., 2002b; Daubin et al., 2002) suggest that there is a phylogenetic framework that reflects the evolution of substantial fractions of bacterial genomes.

Looking Beyond Sequence Evolution

In addition to comparisons of the primary sequences of DNA or proteins, several other molecular, genetic and genomic features have been used to examine the evolutionary relationships among the Bacteria (Eisen, 2000; Wolf et al., 2002). The goal of such studies is to infer a whole-organism (as opposed to a single gene) phylogeny by developing statistics that denote

the overall similarity between entire genomes. To their advantage, these methods do not rely upon the alignments of individual genes or proteins for phylogenetic reconstruction and largely avoid inconsistencies that result from paralogy and lateral transfer unless occurring on a very broad scale. Unfortunately, the rates and patterns of evolution of many of these alternate characters are unclear such that the underlying basis of variation is not known, not specified, or not consistent among taxa. As a result, the reconstructed phylogenies are usually compared with that of SSU rRNA, and any incongruities help model the evolution of a particular trait. For example, if organisms with identical GC contents are unrelated according to their SSU rRNA sequences, the phylogenetic signal of such a character is presumed to be weak and one can conclude that the processes that modulate base composition act somewhat independently of ancestry. The problems (and arguments) arise when discordant phylogenies are inferred from characters that are each assumed to have a common basis in all organisms, to be transmitted strictly vertically, and to be resistant to convergence (such that similar traits could not have arisen independently in different taxa).

Many whole-genome characteristics can provide measures of similarity among organisms that can be used to infer phylogenetic relationships. Early genetic maps showed that both gene contents and gene order are conserved among

closely related organisms (e.g., *E. coli* and *S. typhimurium*) but that the conservation is disrupted with evolutionary distance (e.g., *E. coli* vs. *Bacillus subtilis*). Huynen and Bork (1998) compared the rates of change in gene contents and gene order with that of protein sequence evolution in 9 (8 bacterial and 1 archaeal) fully sequenced genomes. Gene order decayed most rapidly, followed by gene repertoire, and finally protein sequences remained most conserved (implying that these possess the strongest phylogenetic signal for inferring relationships among very divergent organisms). Bacterial genomes have been characterized on the basis of numerous other features, and although no explicit phylogenies are produced, these descriptors have been used to infer the intergenomic differences among organisms (Karin et al., 2002).

Genome Content

In a prevalent whole-genome approach, the degree of similarity between organisms is based on the fraction of genes shared. Whereas the mechanisms by which bacterial genomes can gain or lose genes are well understood, the effects of these processes and the rates at which they occur are highly variable across organisms. Because closely related organisms tend to have many uniquely shared characteristics, one anticipates that their gene contents should be similar; however, the estimated fraction of genes common to two organisms can be greatly affected by differences in genome sizes. In the worst case scenario, if a hypothetical organism contained only the minimal set of universally distributed genes, then, on the basis of its gene contents, this genome would be perceived as being equally similar to all other genomes regardless of its true ancestry. And in the reciprocal comparisons, the fraction of genes shared with this hypothetical organism would be wholly dependent upon the total gene number of a particular organism.

Despite such caveats, many of the whole genome phylogenies based on gene contents resemble those based on SSU rRNA. Naturally, the perceived similarity between genomes is influenced by how shared genes are identified. There are basically two approaches, designated by House and Fitz-Gibbon (2002) as the “homolog” method, which examines the taxonomic distribution of gene families (Fitz-Gibbon and House, 1999) or the representation of a genome in the different clusters of orthologous groups (COGs) of proteins (Tatusov et al., 1997; Lin and Gerstein, 1999; Tatusov et al., 2001; Wolf et al., 2001), and the “ortholog” method, based on the proportion of shared orthologs, usually regarded as sequences that are reciprocally the best matches in a pair of genomes (Snel et al.,

1999; Tekai et al., 1999; Bansal and Meyer, 2002; Clarke et al., 2002; Korbel et al., 2002). The relationships between genomes by the homology method would not be affected by gene duplication or the partial loss of a gene family because these processes do not alter the absolute number of gene families, but this number is sensitive to massive genome reduction (as seen in many parasites and symbionts) and to the acquisition or loss of novel classes of genes. In contrast, the orthology method would be affected by any mechanism that removes orthologs (deletions, nonhomologous gene displacement, etc.) and by recent gene transfers and duplications.

As expected, large genomes have higher numbers of genes or gene families in common (Snel et al., 1999; Lin and Gerstein, 2000; Wolf et al., 2001; Bansal and Meyer, 2002), but when the metric is normalized by genome size, or when microbes with reduced genomes are excluded from the analysis, the distance between genomes more-or-less reflects traditional phylogenetic classifications and subdivisions. The gene-content phylogeny of Snel et al. (1999) is reminiscent of the SSU phylogeny but groups Cyanobacteria with Aquificae at the base of the bacterial tree, whereas a revised version (Huynen et al., 1999), which applies the same orthology approach but includes additional taxa, places Aquificae alone at the base and the Thermotogae with the Spirochaetes. In contrast, the genome content tree of Clarke et al. (2002), which is based on the fraction of ORFs reaching a normalized BLASTP threshold, places Thermotogae as the basal lineage. The gene content phylogenies based on the homology approach are greatly affected by the inclusion of organisms with highly reduced genomes (which tend to group together), and more “phylogenetically reasonable clades” (Wolf et al., 2001) are recovered by omitting these taxa. Looking at the shared occurrence of gene families in the genomes of sequenced, free-living organisms, House and Fitz-Gibbon (2002) place the Aquificae at the base of the bacterial tree, but the branching order of other bacterial phyla remains obscure.

Ortholog Similarity

Although different pairs of orthologs conserved between two genomes can display dissimilar levels of identity as a result of differential functional constraints, the distribution of distances between orthologs should reflect the evolutionary relationship between a given pair of genomes. Several authors (Grishin et al., 2000; Clarke et al., 2002; Wolf et al., 2002) have identified orthologs common to two fully sequenced genomes by searching for the reciprocal best hits and used various measures to convert ortholog similarity

scores to a matrix conveying the pairwise distance between genomes. Depending on which taxa are included in the particular study, the phylogenies extracted from these distance matrices differ in placing Thermotogae, Aquificae or both at the base of the bacterial tree.

Gene Order

Early comparisons of sequenced genomes detected little long-range conservation in gene order (Mushegan and Koonin, 1996), but overlaid on this pattern, there are several gene clusters and gene pairs (mostly involving ribosomal proteins) maintained in all bacterial genomes (Siefert et al., 1997; Dandekar et al., 1998; Wachtershauser, 1998; Wolf et al., 2001). Conservation of gene order seems to reflect the evolutionary distance between organisms (Tamames, 2000; Wolf et al., 2001), but it evolves faster than gene contents (Huynen and Bork, 1998; Korb et al., 2002), and its use as a phylogenetic marker should be limited to comparisons of rather closely related genomes (Suyama and Bork, 2001). Kunisawa (2001) has developed a method for reconstructing phylogenetic relationships based on the physical arrangement of clustered genes, and when applied to members of the Proteobacteria, this method produces a topology that is consistent with the traditional sequence-based classifications.

Other Genome Features

Because of the well-known heterogeneity in the sizes and nucleotide compositions of bacterial genomes, there have been attempts to group bacterial taxa according to total G+C contents, codon usage biases, di- tri- and tetra- nucleotide frequencies (genomic signature abundances), the number and distribution of repetitive sequences, short palindromes and rRNA operons, gene and protein lengths, and amino acid composition (reviewed in Karlin et al., 2002). These approaches have retrieved some intriguing (coincidental?) similarities between genomes that are not typically grouped in sequence-alignment-based phylogenies, but few of these features can be viewed as a consistent and reliable indicator of evolutionary distance because many are susceptible to convergence.

Wolf et al. (1999) and Lin and Gerstein (2000) have taken a unique approach by examining the occurrence of specific protein folds throughout the genome, and the phylogenetic groupings in the resulting “fold” trees are surprisingly similar to those based on SSU rRNA. Several authors have begun to make direct comparisons of the tree topologies of Bacteria recovered from different features of the genome and proteome (Lin

and Gerstein, 2000; Wolf et al., 2001; Wolf et al., 2002). These studies clearly show that some aspects of the genome contribute only weak phylogenetic signals and imply that the addition of characters to an analysis, even those that are known to be genetically determined, will not always increase the accuracy of the tree.

Enterobacteriaceae: What's in a Name?

Even for the most extensively studied group of the Bacteria, recent molecular phylogenetic analyses have revealed some unrecognized kinships between taxa as well as numerous inconsistencies in the present classification scheme. The Enterobacteriaceae are Gram-negative, facultatively anaerobic rods belonging to the γ -class of Proteobacteria. Only a few actually reside in an “enteric” environment; however, most fall within a group of related species that colonize the mammalian intestine. There are currently 41 described genera in *Bergey's Manual of Systematic Bacteriology* 2nd edition (Garrrity, 2001), including species found in terrestrial and aquatic environments, and associated with plants or animal hosts. Members of this family are usually motile, catalase positive, oxidase negative, and use the Embden-Meyerhof pathway to catabolize sugars and to produce acids from the fermentation of glucose. They can be distinguished from other Gram-negative, rod-shaped bacteria (such as those in the families Vibrionaceae and Pasteurellaceae) by cell geometry, flagellar arrangement, oxidase production, sodium requirements and the presence of a common antigen (Brenner, 1981).

Despite these and other shared metabolic properties, assignment of microorganisms to the Enterobacteriaceae no longer requires detailed information about the morphological and biochemical characteristics of an organism. Molecular phylogenetic analyses have now defined the extent of sequence variation within this taxonomic group, and any strain whose sequence falls within this delineated range can be tentatively classified in the Enterobacteriaceae, even without knowledge of its morphology, metabolic capabilities, or growth requirements. Of course, this assumes that the phylogenetic trees and evolutionary relationships based on genes represent those of the organisms themselves, and at least for many of the species constituting the Enterobacteriaceae, the correspondence between the molecular and the original phenotypic classification schemes is rather good. That said, we should note that molecular analyses have revealed that several enteric genera are polyphyletic, such that their constituent species are not derived from a

unique common ancestor. For example, some species of *Klebsiella* and *Enterobacter* are more closely related to one another than to other species typed to the same genus (Harada and Ishikawa, 1997; Mollet et al., 1997; Hauben et al., 1998; Dauga, 2002). Such findings have resulted in the recent reclassification of certain taxa and changes in nomenclature. At present, the determination of a comprehensive phylogeny encompassing all genera within a family cannot yet rely on whole-genome sequencing, and relationships at this and lower taxonomic levels are still determined through single-gene phylogenies, mostly SSU rRNA.

Phylogenetic Analyses of Enterobacteriaceae Based on SSU rRNA

The phylogenetic tree in Fig. 2 displays the evolutionary relationships of many well-recognized genera of Enterobacteriaceae and, for reference, *Haemophilus influenzae* and *Vibrio cholerae*, which are nonenteric members of the γ -Proteobacteria. This phylogeny is derived from SSU rRNA sequences; and in many cases, relation-

ships among the better-studied organisms match those resolved by biotyping. It is evident that certain genera are cohesive and monophyletic, that is, contained within a group that consists of a single common ancestor and all of its descendant organisms. As mentioned above and as previously reported (Hauben et al., 1998; Sproer et al., 1999; Dauga, 2002), *Klebsiella*, *Enterobacter* and *Serratia* are polyphyletic, consisting of species descended from two or more ancestors.

To construct the phylogeny in Fig. 2, SSU rRNA sequences for representatives of all recognized enteric genera (except *Moellerella*, *Saccharobacter*, *Trabulsiella* and *Yokenella* for which cognate sequences are not available) were extracted from GenBank. For several genera, numerous sequences are available (either from multiple species within the genus or from multiple rRNA operons within a genome) yielding a set of 193 enteric SSU rRNA sequences, which were aligned with ClustalX using the default settings (Thompson et al., 1997). Following initial alignment, sequences were removed if they were not full length or if the genera and/or species were not well represented in the literature. Next,

Fig. 2. Phylogeny of Enterobacteriaceae based on small subunit (SSU) rRNA. See text for criteria used to select species and for methods of phylogenetic reconstruction.

^aGenbank accession number of completely sequenced genome.

all but one (or two) sequences were removed from the set for each genus if the multiple representatives for a given genus were found to be monophyletic. The resulting data set contained 27 taxa, including 22 enteric genera (Table 1). The NEXUS file containing these sequences is available at the TreeBase Web site (<http://www.treebase.org>) under Study Accession S801 and Matrix Accession M1267.

To refine the sequence data for phylogenetic analysis, two short regions (positions 70–103 and 461–489) were excluded owing to high levels of sequence and length variation, which made alignments ambiguous. To determine the best-fit model of DNA evolution, the resulting alignments were subjected to hierarchical likelihood ratio tests in Modeltest v3.06 (Posada and Crandall, 1998). For the phylogenetic analyses, a neighbor-joining (NJ) tree was constructed under the general time reversible (GTR) model of evolution (log likelihood = −6952.9580; estimated by Modeltest v3.06) with Phylogenetic Analysis Using Parsimony (PAUP* v4.0b10; Swofford, 2000). The maximum parsimony (MP) analysis was conducted using PAUP* by optimizing characters with accelerated transformation, 10 repetitions of random sequence additions,

starting trees obtained by stepwise addition, and branches swapped by tree bisection-reconstruction. In addition, a Bayesian inference of phylogeny was conducted using MrBayes v2.01 (Huelsenbeck and Ronquist, 2001b). The GTR model, with some sites assumed to be invariant and with variable sites assumed to follow a discrete gamma distribution, was used for all analyses. Bayesian analyses were initiated with random starting trees and run for 1.5 million generations, with a 100 generations sampling interval. Replicates were performed to determine that analyses were not trapped at local optima (Huelsenbeck and Bollback, 2001a). After discarding the initial burn-in samples (the first 5,000 trees), the remaining 10,000 trees were used to generate a 50% majority rule consensus tree using PAUP*, with the percentage of trees containing a node representing that node's posterior probability (Huelsenbeck and Ronquist, 2001b).

Figure 2 represents the most reliable composite estimation of the phylogenetic relationships among enteric bacteria. A time scale for the diversification of bacterial species has been proposed (Ochman and Wilson, 1987; Doolittle et al., 1996) on the basis of the estimated divergence time of 100 million years ago for the split

between *E. coli* and *Salmonella enterica*. If SSU rRNA evolves at approximately the same rate in all enteric taxa (Ochman et al., 1999), then it is possible to estimate the divergence time between any pair of taxa by extrapolation.

Structural RNAs evolve very slowly and are not useful for resolving the relationships among closely related organisms, such as strains within a species or, sometimes, even species within a genus. In addition to SSU rRNA, several other molecules and typing methods have been used to examine relationships among enterics, and below, we briefly discuss the phylogenetic status of species within representative enteric genera:

Escherichia/Shigella The genus *Escherichia* contains five species: *Escherichia blattae*, *E. coli*, *E. fergusonii*, *E. hermannii* and *E. vulneris* whose relationships to one another, and to other enteric species, have been resolved by the phylogenetic analysis of *gapA* and *ompA* sequences (Lawrence et al., 1991). *Escherichia coli* and *E. fergusonii* form a monophyletic clade, with each being more closely related to one another than either is to *Salmonella*; however, the other three species classified in this genus represent a phylogenetically heterogeneous group of organisms. *Escherichia hermannii* is basal to *E. coli*, *Salmonella enterica* and *Citrobacter freundii*; *E. blattae* branches between *Serratia* and *Klebsiella*; and *E. vulneris* is polyphyletic, with one strain grouping with *K. pneumoniae*.

The relationships of thousands of strains of *E. coli* have been determined by multilocus enzyme electrophoresis, and several other typing schemes have examined the genetic variation in clinical, laboratory and natural isolates (Whittam, 1997). It is probably safe to say that more is known about the degree, appointment and maintenance of genetic variation in *E. coli* than in any other bacterial species. The genera *Escherichia* and *Shigella* were grouped together by DNA-DNA hybridization studies, which demonstrated that they belonged to the same genetic species (Brenner et al., 1972; Brenner et al., 1973). Subsequent analyses have shown that the variation within the four recognized species of *Shigella* (*S. dysenteriae*, *S. flexneri*, *S. boydii* and *S. sonnei*) is contained within that observed in *E. coli*, i.e., strains of *Shigella* have arisen through multiple independent origins from within *E. coli* (Ochman et al., 1983; Pupo et al., 1997; Pupo et al., 2002).

Salmonella The genus *Salmonella* is monophyletic and comprises two species, *Salmonella bongori* and *S. enterica*. The separation of *S. bongori* from *S. enterica* has been confirmed by DNA-DNA hybridization (Le Minor et al., 1982), phylogenetic analyses of housekeeping and rRNA

genes (Selander et al., 1996; Christensen et al., 1998b). *Salmonella bongori* is considered to be a homogenous group (Hoszkowski and Wasyl, 2000), whereas *S. enterica* is subdivided into seven subspecies, enumerated as I, II, IIIa, IIIb, IV, VI and VII, which encompass more than 2,000 serovars. Most human pathogens (e.g., Typhi) belong to subspecies I. The relationships within *Salmonella* have been derived from multilocus enzyme electrophoresis and by the analysis of several genes, which have been sequenced in each of the subspecies type strains constituting the *Salmonella* Reference Collection (SARC; Boyd et al., 1996; Brown et al., 2002).

Erwinia/Pectobacterium/Brenneria/Pantoea Originally, the genus *Erwinia* was divided into two taxonomic groups, *amylovora* and *carotovora*, on the basis of phytopathogenicity properties (Brown et al., 2000). The *amylovora* group is considered less metabolically active and requires organic nitrogen for growth, whereas the *carotovora* group has higher metabolic activity, reduces nitrates to nitrites, and causes soft-rot diseases (Brenner, 1981). Subsequently, phylogenetic analyses of SSU rRNA demonstrated that the genus *Erwinia* was polyphyletic, which led to the partitioning of *Erwinia* into three genera: *Erwinia*, *Pectobacterium* and *Brenneria* (Hauben et al., 1998). The genera *Erwinia* and *Brenneria* contain the necrogenic phytopathogens (formerly the *amylovora* group) and *Pectobacterium* encompasses the soft-rotting phytopathogens (formerly the *carotovora*). An additional group of phytopathogens closely related to *Erwinia* has been assigned to the genus *Pantoea*.

Serratia Members of the genus *Serratia* can be found in environmental samples, as well as in association with human disease. There are nine described species within the genus: *Serratia odorifera*, *S. marcescens*, *S. rubidaea*, *S. entomophila*, *S. ficaria*, *S. fonticola*, *S. plymuthica*, *S. proteamaculans* and *S. grimesii* (Sproer et al., 1999). Phylogenetic analyses of SSU rRNA sequences suggest that *Serratia* is polyphyletic, with one cluster more closely related to *Hafnia alvei* and *Obesumbacterium proteus*, than to the other *Serratia* cluster (Sproer et al., 1999). In contrast, phylogenetic analyses of the sequences encoding the ATPase domain of DNA gyrase (*gyrB*) showed *Serratia* to contain two clusters forming a monophyletic group (Dauga, 2002).

Klebsiella Klebsiellae are detected in environmental samples as well as on the mucosal surfaces of mammals. Certain species are opportunistic pathogens and are associated with respiratory diseases and urinary tract infections in humans (Podschun and Ullman, 1998). The

five most common species are *Klebsiella aerogenes*, *K. edwardsii*, *K. pneumoniae*, *K. ozaenae* and *K. rhinoscleromatis*, and in some classifications, *K. edwardsii* and *K. pneumoniae* are subdivided into additional subspecies (Podschun and Ullman, 1998). Phylogenetic analyses of SSU rRNA (Hauben et al., 1998), translation initiation factor 2 (*infB*; Hedegaard et al., 1999), RNA polymerase β -subunit (*rpoB*; Mollet et al., 1997), *groE* (Harada and Ishikawa, 1997) and *gyrB* (Dauga, 2002) all suggest that the genus is polyphyletic. In these studies, some species of *Klebsiella* were more closely related to members of the genus *Enterobacter* than to other *Klebsiella* species (Hauben et al., 1998; Dauga, 2002). In light of this evidence, there is a need to reclassify the members of this genus in a way that reflects their molecular relationships.

Enterobacter The *Enterobacter* occupy similar environmental and ecological niches as *Klebsiella*. There are 16 described species within the genus, and as with *Klebsiella*, the genus *Enterobacter* is polyphyletic. On the basis of the phylogenetic analyses of nucleic acid and protein-coding sequences, certain *Enterobacter* species should be grouped with *Klebsiella*. For example, *E. aerogenes* falls in a clade with *Klebsiella pneumoniae* rather than with *E. cloacae* in phylogenies based on SSU rRNA and *gyrB* sequences (Dauga, 2002).

OTHER ENTERIC GENERA Some of the other members of the Enterobacteriaceae exhibit a wide range of associations with eukaryotic hosts, ranging from opportunistic pathogens to mutualistic symbionts. Some examples of pathogens include *Edwardsiella* (which are pathogenic to fish), certain *Yersinia* and *Citrobacter* (which cause diarrhea and disease in humans), and *Proteus* (which induce otitis in dogs). In contrast, *Photorhabdus* and *Xenorhabdus* consist almost entirely of mutualistic symbionts of the nematode genera *Steinernema* and *Heterorhabditis* (Boemare et al., 1993). These symbionts serve to maintain conditions conducive for nematode reproduction (Poinar and Thomas, 1966; Poinar and Thomas, 1967) and produce antimicrobial compounds that inhibit the growth of other microorganisms (Akhurst, 1983; Boemare et al., 1993).

The phylogenetic relationships within several of these enteric genera have been analyzed using SSU rRNA sequences (e.g., *Buttiauxella* [Sproer et al., 1999], *Photorhabdus* and *Xenorhabdus* [Suzuki et al., 1996; Liu et al. 1997], and *Yersinia* [Ibrahim et al., 1993]). And for those enteric genera containing but a single species (e.g., *Calymmatobacterium* [Kharsany et al., 1999], *Candidatus Phlomobacter fragariae* [Zreik et al.,

1998], and *Hafnia* [Hauben et al., 1998; Sproer et al., 1999]), relationships to other members of the Enterobacteriaceae (as well as identification as unique genera) have typically been established by the analysis of SSU rRNA sequences.

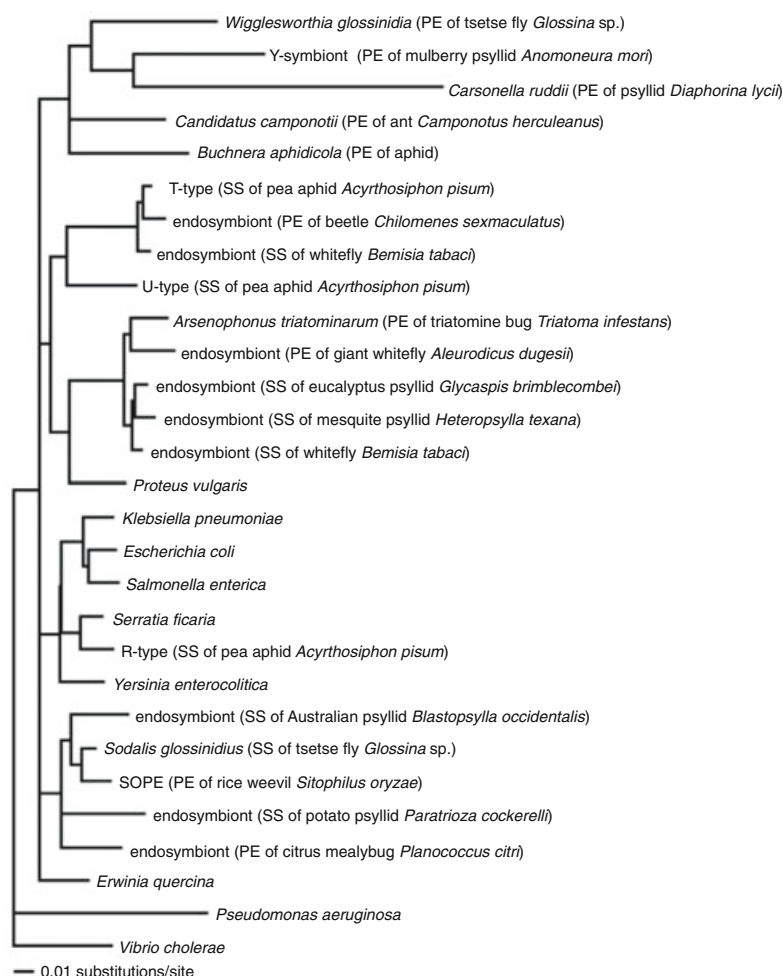

The Emergence of Bacterial Symbionts

The characterization of bacterial symbionts, which are broadly distributed and cannot be maintained outside of their animal hosts, has been one of the greatest successes of culture-independent methods for the identification and classification of microbes. Insects that feed exclusively on blood or plant sap contain obligate (primary) symbionts that offset their host nutritional deficiencies, reside within specialized host organs, and are essential for host survival. In addition to these primary symbionts, many insects contain secondary symbionts that confer no obvious benefit to their host, are not essential for either host growth or reproduction, and invade a diverse range of host tissues. Whereas primary symbionts are strictly vertically transmitted within a host lineage, sometimes for hundreds of millions of years (as evident from the concordance between symbiont and host phylogenies), secondary symbionts can be horizontally transmitted among insect host species (Moran and Baumann, 2000).

Molecular phylogenetic analyses have provided evidence that the majority of primary and secondary symbionts of insects have evolved from within the Proteobacteria, and in particular the γ -Proteobacteria (Fig. 3). To show the relationships of symbiotic lineages to the Enterobacteriaceae, we included several enteric species in this phylogeny and rooted this tree with *Vibrio cholerae*, which also serves as an outgroup to the enteric bacteria (Fig. 2).

The evolution of symbionts from free-living proteobacterial ancestors often involves a vast reduction in genome size; in fact, at 440 kb, the bacterial symbiont of aphids has the smallest known genome for a cellular life form (Gil et al., 2002). As is apparent from this phylogeny, the origin of new symbiotic species can occur by two routes: 1) the independent derivation of symbionts from free-living ancestors, and 2) the diversification from within a clade that is already symbiotic (usually associated with the infection of a new host species). The molecular genetic information for most of the symbionts included in Fig. 3 is presently limited to SSU rRNA sequences; however, their small genome sizes and limited gene repertoires make many of these bacteria ideal subjects for genome projects.

Fig. 3. Small subunit (SSU) rRNA phylogeny of γ -proteobacterial symbionts and related free-living species. Many symbionts have no official nomenclature and are listed according to their designations in the literature or in sequence databases. Common names and Latin binomials of hosts are given. PE, primary endosymbiont; SS, secondary symbiont.

The Genus *Escherichia*

RODNEY A. WELCH

Introduction

Escherichia coli, originally called “*Bacterium coli* commune,” was first isolated from the feces of a child in 1885 by the Austrian pediatrician Theodor Escherich (Escherich, 1885). *Escherichia coli* is a common inhabitant of the gastrointestinal tract of humans and animals. There are *E. coli* strains that are harmless commensals of the intestinal tract and others that are major pathogens of humans and animals. The pathogenic *E. coli* are divided into those strains causing disease inside the intestinal tract and others capable of infection at extra-intestinal sites (Kaper et al., 2004). *Escherichia coli* is easily cultured in the clinical laboratory, but the identification of the different pathogenic genotypes requires virulence gene detection methods not typically available in most clinical laboratories. *Escherichia coli* can be found secondarily in soil and water as the result of fecal contamination. Classically, its detection has been used as an indicator of poor water quality. From biochemical, physiological and genetic perspectives, *E. coli* is one of the best understood and characterized living organisms, with laboratory studies on model strains such as *E. coli* K-12 taking place over the past sixty years (extensively reviewed in *Escherichia coli* and *Salmonella: Cellular and Molecular Biology*, third edition; available online through the <http://www.asmpress.org/browse/virtual/index>.

[asp?SelectedItem=10075{ASM Press Web site}}](#)). Shown in Table 1 are additional websites providing general and specific *E. coli* portals for useful genetic and metabolic information.

Taxonomy and Phylogeny

General Comments

The comparative analysis of 5S and 16S ribosomal RNA sequences suggest that *Escherichia* and *Salmonella* diverged from a common ancestor between 120 and 160 million years ago, which coincides with the origin of mammals (Ochman and Wilson, 1987). *Escherichia* and *Shigella* have been historically separated into different genera within the Enterobacteriaceae. DNA sequence analysis of their genomes reveals a high degree of sequence similarity and suggests to many bacteriologists that they should be considered a single species (see *Shigella* genome references: Ewing et al., 1958; Kimura, 1980; Brenner, 1984; Saitou and Nei, 1987; Simmons and Romanowska, 1987; Nei and Miller, 1990; Pupo et al., 2000; Jin et al., 2002; Wei et al., 2003). Currently, the two organisms continue to be discussed as two different genera anchored in the historical perception of their disease potential and ecology. Besides *E. coli*, there are other species within the genus, *E. adecarboxylata*, *E. blattae*, *E. fergusonii*, *E. hermannii* and *E. vuln-*

eris. Little is known about the distribution, biology or interrelatedness of these species.

Escherichia coli Clonality

Evolutionary studies based on either DNA sequence analysis or multilocus enzyme electrophoresis has identified clonal phylogenetic groupings of *E. coli*. Phylogenetic studies have principally used the *E. coli* reference (ECOR) strain collection as a common reference for current evolutionary comparisons (Ochman and Selander, 1984). This collection can be acquired from Thomas Whittham's laboratory (<http://foodsafety.msu.edu/whittam/ecor/>). Six phylogenetic groups are generally recognized among the ECOR strains (A, B1, B2, C, D and E; Selander et al., 1987; Fig. 1). For the phylogenetic groups, there are some general biotype clusterings (e.g., raffinose fermentation is common among B1, C, D and E strains, whereas sorbose fermentation is common to B2 strains; Miller and Dancel, 1986). There are limited instances where host sources are associated with clonal types. For example, among the original B1 strains, many were commonly isolated from herbivores (Selander et al., 1987). In general, however, there is notably little association between host strain source and clonal designation.

Evolution of Pathogenic Types (Pathotypes) of *E. coli*

Virulent strains of *E. coli* are differentiated clinically from one another on the basis of epidemiology, signs and symptoms of their respective diseases, microscopic observations of their interactions with host cells, and of biotypes and unique gene markers. The specifics for each of the *E. coli* pathotypes will be discussed in the disease topic below. The evolution of independent pathogenic types of *E. coli* is striking and to date unmatched by any other bacterial genus. How this occurred is unclear, but it is likely linked to the concomitant evolution of different mammalian hosts. Initially isolates involved in both intestinal and extra-intestinal human disease were thought to be concentrated mostly within the single, B2 ECOR phylogenetic group with a smattering of isolates found in the D group. However, recent studies indicate that extensive horizontal transmission of blocks of genes has occurred across the different phylogenetic clonal lines. Thus, with the possible exception of the enterohemorrhagic *E. coli* O157:H7, many of the *E. coli* pathotypes apparently do not have unique evolutionary origins. The virulent *E. coli* strains have arisen independently on multiple occasions within clonal lines (Pupo et al., 1997). On the basis of the relative number of

isolates identified within the general diarrheagenic and extra-intestinal pathotype groupings, the former are more frequently found in the A, B1 and D phylogenetic groups, whereas the extra-intestinal *E. coli* strains are more common to the B2 lineage (Johnson, 2002).

Evolution of the *E. coli* Genome

Genome sequencing of three different *E. coli* strains (laboratory K-12 strain MG1655, enterohemorrhagic O157:H7 strain EDL933, and an uropathogenic isolate, CFT073) reveals an unambiguous conservation of nearly 40% of the core gene sequences among the three isolates (Welch et al., 2002). The synteny of the genes around the circular chromosomes is nearly intact and representative of the classic *E. coli* K-12 gene map (Berlyn, 1998). The phylogenies used to build the ECOR phylogeny is also reflected in the relatively slow divergence of the core gene sequences. The general conservation of genes among the three isolates undoubtedly reflects the physiological nature of what can be termed “*E. coliness*.” *Escherichia coli*, even the pathogenic types, at some point thrive in a mammalian intestine, yet they are also capable of surviving periods in the outside environment. However, there is striking evidence that concurrent with the vertical evolutionary processes that account for the ECOR-based phylogenetic differences, horizontal genetic transfer has occurred frequently and had the greatest impact on genetic differences among strains. Comparisons of one genome with another reveal hundreds of instances where insertions, substitutions and deletions of large blocks of DNA have disrupted the order of the core genes. For example, the CFT073 genome is nearly 600 kbs larger than MG1655, and in one-on-one comparisons, there are approximately 1100 genes unique to K-12 and greater than 1800 genes unique to CFT073 (Fig. 2). The majority of the unique genes are on segments that vary from 4 kb to over 100 kb. Aside from complete and partial prophages, the largest blocks of strain-specific genes share some common features. They are often located at tRNA genes (e.g., *leuX*, *selC*, *argW*, *pheV* and *pheU*). The G+C content is often lower than the typical 50–52 mol% for the core genes. The predicted codons used in the EDL933 or CFT073 strain-specific genes is skewed towards greater use of tRNAs typically less abundant than those involved in *E. coli* K-12 translation. These observations suggest that the larger gene blocks originate in and are mobilized from genera much different than any of the close relatives of *E. coli* (such as *Salmonella*). Prior to genomic sequencing, it was recognized that many of the most significant virulence genes (adhesins, extracellu-

Fig. 2. Shared *E. coli* proteins. Comparison of the predicted proteins of the three *E. coli* strains shows the number of orthologs in each shared category and numbers of strain-specific proteins. Hypervariable proteins and proteins extending across junctions between island and backbone sequences were excluded from the analysis. Number of proteins counted: K-12 (4288), CFT073 (5016), and EDL933 (5063). In the totals for the three strains, orthologous proteins are counted only once. Orthologous proteins meet the same match criteria used for designation of the backbone.

lar protein secretion systems, and toxins) for several *E. coli* pathotypes were clustered together in these large blocks. Hacker and colleagues coined the term “pathogenicity-associated islands” (PAIs) to describe these Hacker et al., 1997). Still unclear is whether much of the added, unique genetic material has anything to do with pathogenicity. Thus, the unique gene clusters are often simply and appropriately called “genetic islands.” The ability to build a phylogeny for some of the *E. coli* pathotypes is complicated because the horizontally acquired islands do not always share chromosomal location and genetic content (Welch et al., 2002).

Habitat

Escherichia coli are common inhabitants of the terminal small intestine and large intestine of mammals. They are often the most abundant facultative anaerobes in this environment. They can occasionally be isolated in association with the intestinal tract of nonmammalian animals and insects. The presence of *E. coli* in the environment is usually considered to reflect fecal contamination and not the ability to replicate freely outside the intestine. There is evidence however to suggest that *E. coli* may freely replicate in tropical fresh water (Bermudez and Hazen, 1988).

Cell Structure

Escherichia coli are Gram-negative, nonspore-forming bacilli. They are approximately 0.5 μm in diameter and 1.0–3.0 μm in length. Within the periplasm is a single layer of peptidoglycan. The

peptidoglycan has a typical subunit structure where the *N*-acetylmuramic acid is linked by an amide bond to a peptide consisting of L-alanine, D-glutamic acid, *meso*-diaminopimelic acid and finally D-alanine.

Escherichia coli are commonly motile in liquid by means of peritrichous flagella. Swarming behavior and differentiation into hyperflagellated and elongated bacilli typical of that seen with the *Proteus* species can be observed on some solid media (Harshey, 1994). *Escherichia coli* are commonly fimbriated. The type 1 pili are the most common and are expressed in a phase switch ON or OFF manner that leads to piliated and nonpiliated states (Eisenstein, 1987). One of the traits commonly encoded on the larger genetic islands of the different pathotypes of *E. coli* are additional pili (chaperone-usher and type IV pili families and non-pili adhesins; Bann, 2002; Schreiber and Donnenberg, 2002).

Among *E. coli* isolates, there is considerable variation and many combinations of somatic (O and K) and flagellar (H) antigens. Among pathogenic strains, there are few patterns of these antigens and few phylogenetic groupings (see below). For *E. coli*, there are over 150 antigenically unique O-antigens (Whitfield and Valvano, 1993). K type capsular material occurs in two or four forms on the basis of physical, biochemical and genetic criteria (Jann and Jann, 1990; Whitfield and Roberts, 1999). Over 80 serologically and chemically distinct capsular polysaccharides have been reorganized (Jann and Jann, 1992). In addition, a slime layer, colonic acid extracellular polysaccharide, is common to many *E. coli* isolates and can be co-expressed with some K-type capsules (Keenleyside et al., 1993). There are 53 H-antigen specificities among *E. coli* (Wang et al., 2003).

Cell Physiology

Escherichia coli is a facultative anaerobe. It is capable of reducing nitrates to nitrites. When growing fermentatively on glucose or other carbohydrates, it produces acid and gas. By traditional clinical laboratory biochemical tests, *E. coli* is positive for indole production and the methyl red test. Most strains are oxidase, citrate, urease and hydrogen sulfide negative. The classic differential test to primarily separate *E. coli* from *Shigella* and *Salmonella* is the ability of *E. coli* to ferment lactose, which the latter two genera fail to do. Aside from lactose, most *E. coli* strains can also ferment D-mannitol, D-sorbitol, and L-arabinose, maltose, D-xylose, trehalose and D-mannose. There are limited instances where pathogenic strains differ from the commensals in their metabolic abilities. For example, commensal *E. coli* strains generally use sorbitol, but *E.*

coli O157:H7 does not. Most diarrheagenic strains cannot utilize D-serine as a carbon and nitrogen source, but uropathogenic and commensal fecal strains can use this enantiomer of serine (Roesch et al., 2003).

Most *E. coli* strains are capable of growing over a wide range in temperature (approximately 15–48°C). The growth rate is maximal in the narrow range of 37–42°C (Ingraham and Marr, 1987). *Escherichia coli* can grow within a pH range of approximately 5.5–8.0 with best growth occurring at neutrality. Some diarrheagenic *E. coli* strains have the ability to tolerate exposure to pH 2.0. Such an acid shock mimics transit through the stomach and induces expression of sets of genes involved in survival and pathogenesis (Waterman and Small, 1996).

There are several sources of information on genes identified as essential for growth of laboratory strain K-12. Efforts are underway to identify essential genes for drug target studies, as well as to construct a freely replicating *E. coli* strain with the smallest possible genome. The study of such an engineered strain would simplify the analyses of regulatory circuits and mechanics of fundamental processes such as cell division and chromosomal replication (Gerdes et al., 2003); information on the topic with links can be found at the (<http://www.genome.wisc.edu/resources/essential.htm>{University of Wisconsin Essential genes in *E. coli* Web site}). information about profiling the *Escherichia coli* chromosome can be found at the (<http://www.shigen.nig.ac.jp/ecoli/pec/index.jsp>{Shigen *E. coli* Web site}).

Iron metabolism of *E. coli* is an especially well-studied topic (Braun and Braun, 2002). Ferric iron is brought into *E. coli* by chelating compounds such as citrate, enterobactin, aerobactin, yersinabactin and heme. These chelators each have highly specific outer membrane proteins that enable their uptake across the outer membrane where they are then brought across the cytoplasmic membrane by ATP binding cassette (ABC) transport systems. One trait that sets many of the pathogenic *E. coli* apart from the normal intestinal *E. coli* is the ability to acquire ferric iron from a wide array of chelators. The multiple gene systems enable adaptation to sites where iron might be limited by host antibacterial activities (Torres et al., 2001). These virulence-enhancing iron acquisition systems, such as aerobactin, are often encoded by plasmids or are present on pathogenicity islands.

Genetics

A great deal of what is known about bacterial genetics comes from the study of the *E. coli* laboratory strain K-12. K-12 was isolated in 1922

from the stool of a convalescent diphtheria patient (Lederberg, 1951). Although K-12 strains are rough in terms of their O-antigen, physical and genetic analyses indicate that the original K-12 parent was likely to have been an O16 strain (Liu and Reeves, 1994). In general, wild strains of *E. coli* are capable of gene transfer by conjugation and transduction, albeit at rates that are greatly reduced when compared to K-12 laboratory events. Natural competency for DNA transformation has not been observed for *E. coli*, although genes similar in sequence to *Hemophilus influenza* competence genes are present in the *E. coli* K-12 genome (Finkel and Kolter, 2001). In the laboratory, artificial methods such as electroporation enable the uptake of DNA and its stable maintenance through recombination or replication as a plasmid or prophage. Conjugal, as well as nonconjugal, plasmids are commonly found in wild strains of *E. coli*.

Ecology

Escherichia coli strains are commonly carried in the mammalian intestine. Usually a predominant clone can be found at any given time, but other less abundant clones can be found simultaneously. Whittham's lab demonstrated that in a study of healthy 3–6 year old girls the most abundant *E. coli* clones varied when examined on a weekly basis. In some rare instances a single clone could be found over a 4-week period, and in others an individual may have as many as 16 different clones over the same period. The average was three clones per girl over the 4-week period. Therefore, the *E. coli* strains found in the intestine are multiclonal and fluctuate in their predominance over time. Colonization of the periurethral area or urinary tract occurs briefly, and the strains isolated at these sites are usually not the predominant clone in the stool at the same time (Schlager et al., 2002).

Aside from adhesins and metabolic traits that would favor one *E. coli* strain over another in their ability to colonize particular sites, the production and immunity to bacteriocins undoubtedly affects the dynamics of the persistence and dominance of individual strains (Riley and Gordon, 1999). Bacteriocin production may give a special competitive advantage in nutrient-poor environments (Riley and Gordon, 1999).

Disease

Escherichia coli Pathotypes

One of the most notable features of *E. coli* is broad diversity of disease-causing genotypes. As

mentioned above, the diseases can encompass different symptoms and gastrointestinal tract pathologies, but there are also diseases at extraintestinal sites. These different genotypes and their disease-causing abilities lead to categories of *E. coli* often referred to as pathotypes. There are six intestinal and two extraintestinal pathotypes currently recognized (Nataro and Kaper, 1998a; Nataro et al., 1998b; Schreiber and Donnenberg, 2002; Kaper et al., 2004). Enterotoxigenic *E. coli*.

A frequent cause of diarrhea in both humans and animals, enterotoxigenic *E. coli* (ETEC) are estimated to cause 600 million cases of human diarrhea and 800,000 deaths worldwide principally in children under the age of 5 (World Health Organization, 1999). Economically significant ETEC diarrheal disease in animals occurs in neonatal calves, pigs and lambs. ETEC cause watery diarrhea that can be mild in nature or in some instances can be a severe, cholera-like illness where rapid dehydration can be life-threatening. In endemic areas of ETEC-mediated diarrhea, infants and children under the age of 5 are the most commonly affected. ETEC exposure in endemic areas is one of the most common causes of traveler's diarrhea.

One of the principal virulence factors for this pathogen is the heat-labile enterotoxin (LT), which interestingly shares structural and functional similarity to the *Vibrio cholerae* cholera toxin (Sixma et al., 1991; Sixma et al., 1993; Spangler, 1992). LT has a classic AB toxin subunit holotoxin structure. The B subunits (as a pentamer) bind to host cell surface GM1 and GD1b gangliosides and the A subunit enzymatically ADP-ribosylates the α -subunit of stimulatory G protein. This G protein regulates host cell adenylate cyclase and LT-mediated modification leads to its permanent activation and an increase in intracellular cAMP levels. This eventually leads to activation of the chloride ion channel of the intoxicated cells, increased chloride ion secretion into the intestinal lumen, and decreased sodium and chloride absorption. The overall result is to reverse the normal intestinal osmotic gradient and cause a net water loss into the gut lumen. Aside from LT, many ETEC strains also express heat-stable enterotoxins (STs), which also contribute to the watery diarrhea. There are two structurally distinct STs, STa and STb. The STs are small polypeptides that share the common features of heat stability and multiple intramolecular disulfide bonds. The action of STa is well understood. It binds to the extracellular domain of plasma membrane-embedded guanylate cyclase. The ETEC toxins are secreted in the terminal small intestine where the ETEC adhere by expression of a complex and diverse group of surface proteins commonly

referred to as “colonization factors” (Gaastra and Svennerholm, 1996).

Enteropathogenic *E. coli*

These organisms are a significant cause of infant diarrhea in developing nations. Enteropathogenic *E. coli* (EPEC) were historically recognized on the basis of serotypes such as O55:H6 and O127:H6. They are currently defined as those diarrheagenic *E. coli* strains that cause attaching and effacing (A/E) lesions on intestinal epithelium but which lack Shiga toxins (verotoxins). There is a great diversity of the *E. coli* serotypes that possess these features. This makes the serotype classification scheme ineffective and indicates that there may be a diversity of pathogenic mechanisms and evolutionary lineages. EPEC disease is generally the result of growth of EPEC in the small intestine. EPEC cause a watery diarrhea that may contain mucus but typically does not have blood in it. Vomiting, fever, malaise and dehydration are also associated. The symptoms may last for a brief period of several days, although instances of long, chronic EPEC disease have been noted.

Some of the mechanisms of EPEC pathogenesis are well understood. For example, the A/E lesion is the result of a complex system of EPEC proteins that are injected into the host intestinal epithelial cell. The A/E lesion represents a dramatic rearrangement of the epithelial cytoskeleton where there is an accumulation of actin directly below the attached EPEC cell. This is often described as an actin pedestal for the attached bacterial cell. There is a specific pathogenicity island, termed the “locus of enterocyte effacement” (LEE), that encodes the genes responsible for the A/E lesion (McDaniel et al., 1995). The LEE encodes a type III secretion system that provides the intimate adhesin, its receptor (which is injected into and then presented on the surface of the host cell), and the injected proteins responsible for changes in host cell signaling mechanisms (including actin pedestal formation; Jerse, 1990; Kenny et al., 1997). Common to most EPEC strains are plasmids, termed “EAF” (“EPEC adherence factor”) plasmids, which encode an adherence factor, the bundle-forming pilus (bfp; Nataro et al., 1987; Donnenberg and Kaper, 1992; Sohel et al., 1996). Results of human volunteer studies indicate the EAF plasmid is necessary to cause disease (Levine et al., 1985). Although the A/E characteristic is critical for causing EPEC disease, probably through destruction of microvilli, the precise mechanism for the diarrhea is not completely understood and may reflect the diversity of EPEC strains. For example, some but not all EPEC produce an enterotoxin, EspC (Mellies, 2001).

Recent attention has focused on greater understanding of atypical EPEC strains (Trabulsi et al., 2002). These strains more commonly cause diarrhea in industrialized nations than the typical EPEC strains. In addition the atypical EPEC strains have animal and human reservoirs, whereas the typical isolates are almost always associated with human fecal contamination. The atypical isolates have the ability to cause A/E lesions but lack the EAF plasmids. They often have additional virulence factors not seen among the typical strains. For example, they have significant portions of the pO157 virulence plasmid common to enterohemorrhagic *E. coli* O157:H7 strains and may have a heat stable enterotoxin (EAST-1).

Enterohemorrhagic *E. coli*

These organisms share the ability to cause A/E lesions with EPEC but enterohemorrhagic *E. coli* (EHEC) are set apart from EPEC by possession of Shiga-like toxins and the clinical presentation of their disease. EHEC cause disease of the large intestine that may present as simple watery diarrhea and then progress to bloody stools with ulcerations of the bowel. In a small subset of diseased individuals there is onset several days later of severe, life-threatening hemolytic-uremic syndrome (HUS). HUS involves a triad of hemolytic anemia, thrombocytopenia and renal failure. The transmission of EHEC disease in humans is through ingestion of contaminated beef or foods contaminated with cattle feces. In cattle, the EHEC strains are transient members of the intestinal microflora where they do not apparently cause disease. One of the remarkable features of EHEC is its low infection dose of 10–100 organisms. Clearly this microorganism has special acid-tolerance ability when compared to many other enteric bacterial pathogens. Children under the age of five are the major victims of EHEC disease, although the elderly may also exhibit bloody diarrhea and HUS. Epidemiologically in the United States, Japan, and Great Britain, a single serotype O157:H7 is the most common EHEC strain. In other parts of the world, this strain can be observed causing disease, but other serotypes (e.g., O26 and O111) cause a similar disease as well.

All factors that lead to HUS are unknown except Shiga toxin (sometimes referred to as “Shiga-like toxin” or “verotoxin”), which probably plays an important role in renal injury. Purified Stx-1 injected intravenously in baboons leads to renal disease with histopathology similar to EHEC-mediated HUS (Tailor et al., 1999). The Shiga toxin inhibits protein synthesis through cleavage of ribosomal RNA. Because EHEC do not cause bacteremia, Shiga toxin is thought to

be released while the organism is growing in the large bowel, where it gets disseminated systemically to cause damage to renal endothelial cells and release of inflammatory mediators that eventually damage the kidney. There are two evolutionarily related forms of Shiga toxin in *E. coli* (Shiga toxin 1 and Shiga toxin 2). They share approximately 55% amino acid sequence similarity. Shiga toxin 1 is only different from the Shiga toxin of *Shigella dysenteriae* by a single amino acid substitution.

There are many Shiga toxin positive *E. coli* strains (STEC) that are not associated with enterohemorrhagic colitis. It is a heterogeneous group that is occasionally associated with HUS, but their general benign nature may be due to their lack of the LEE pathogenicity island and plasmid virulence factors. The ubiquitous dissemination of the distribution of Shiga toxin genes among *E. coli* strains is due to their transmission as part of lambdoid phages. The EHEC O157:H7 strain likely originated in an O55 EPEC strain where a series of genetic events lead to acquisition of shiga toxin-encoding prophages and a large virulence plasmid, pO157 (Reid et al., 2000; Lathem et al., 2003). The precise role of pO157 in EHEC pathogenesis is unknown but may involve some putative toxin genes and a mucin-specific zinc metalloprotease, StcE (Burland et al., 1998; Lathem et al., 2002; Grys et al., 2005).

Enteroaggregative *E. coli*

These organisms are defined as *E. coli* that do not possess LT enterotoxin or Shiga toxins but adhere to cultured HEp-2 cells in self-aggregates that are classically referred to as “stacked bricks” (Nataro et al., 1987). Clearly, many *E. coli* strains can mediate the “stacked brick” adhesive phenotype, but there is a subset of these that are bona fide human diarrheal pathogens. Enteraggregative *E. coli* (EAEC) disease, as described by human volunteers, is a watery diarrhea that occurs in some cases with abdominal cramps, but no fever (Nataro et al., 1995). There is no invasion of the bloodstream. The disease seen in natural EAEC outbreaks is often reported as a persistent, seemingly chronic watery diarrhea. These small epidemics occur in both developing as well as industrialized countries. There are no common serotypes of EAEC to aid in their recognition in the clinical laboratory. The pathogenesis of EAEC disease is poorly understood, although several potential virulence factors are common to EAEC isolates. EAEC express a fimbrial adhesin called “aggregative adherence fimbriae” (“AAF”). EAEC isolates often produce a mucinase called “Pic” whose gene has the ability to express from its nonencoding DNA strand a

smaller gene that encodes an enterotoxin (*Shigella* enterotoxin [ShET1]) first described in *Shigella* strains. EAEC strains often produce a heat stable enterotoxin EAST1 that is homologous to the ST1 of ETEC.

Diffusely Adherent *E. coli*

The epidemiology and pathogenesis of the diffusely adherent *E. coli* (DAEC) are not well understood. DAEC may cause diarrhea in very young children (less than a year old; Scaletsky et al., 2002). They are differentiated from the other diarrhegenic *E. coli* by a distinct adhesion phenotype, again on HEp-2 cells. The adhesion is brought about by F1845 fimbriae, which belong to the Dr family of adhesins (also found in some UPEC strains). The Dr adhesins recognize and bind to host cell surface decay accelerating factor (DAF). DAEC bound to cultured cells elicit a cytopathic phenotype and activation of signal-transduction pathways. The relative significance of DAEC as a pathogen and its mechanisms for causing disease await further study.

Enteroinvasive *E. coli*

These organisms are pathogenetically so closely related to *Shigella* species that the nomenclature distinction is questionable. There are a few biochemical traits that can be used to distinguish enteroinvasive *E. coli* (EIEC) from *Shigella*, but the principal virulence genes are shared. The diagnostic confusion between *Shigella* and EIEC is evident in that EIEC isolates are nonmotile and 70% are nonlactose fermenters (Silva et al., 1980). In addition, EIEC share with *Shigella* the inability to decarboxylate lysine, a trait common to other *E. coli*. The traits that EIEC share with *E. coli* but not *Shigella* are the ability to produce gas from glucose and fermentation of xylose.

EIEC cause invasive inflammatory colitis and dysentery with a clinical presentation (blood and mucous stools accompanied by fever and severe cramps) identical to the disease caused by *Shigella* species. EIEC/*Shigella* invade intestinal epithelium, principally in the large intestine. Once inside the cells, they lyse the phagocytic vesicle and replicate freely in the host cell cytoplasm. The EIEC/*Shigella* cells then spread to neighboring host cells by a motility process whereby actin is nucleated on one pole of the bacillus and subsequent actin polymerization propels the bacterial cell (Goldberg and Theriot, 1995). Many of genes necessary for cellular invasion and disease are carried on a large >200-kb plasmid found in both EIEC and *Shigella*. A system of type III secretion genes important for delivery of modifiers of host cell signaling and membrane lysis are found on these plasmids. In

addition, the plasmid encodes an outer membrane protein (IcsA) that is localized on one pole of the bacterium and directs the actin microfilament polymerization necessary for spread of bacteria to other host cells. EIEC/*Shigella* rarely invade the bloodstream, but they do invade the lamina propria immediately under the intestinal epithelium, where interaction with macrophages causes the release of pro-inflammatory mediators and even induction of apoptosis. Interestingly, the inability to decarboxylate lysine, a trait shared by EIEC and *Shigella*, is the result of mutations and gene rearrangements at the *cadC* gene. The decarboxylation of lysine results in cadaverine, which acts as an inhibitor of inflammation and migration of neutrophils into the lamina propria. The lack of this function is hypothesized to be a pathoadaptive trait that enables EIEC/*Shigella* to cause disease (Maurelli et al., 1998; Fernandez et al., 2001; Casalino et al., 2003).

EXTRAIESTINAL *E. COLI* Two separate pathotypes of *E. coli* are generally recognized causes of extraintestinal human diseases (neonatal septicemia/meningitis *E. coli* [meningitis-associated *E. coli*, MAEC] and the urinary tract and bloodstream *E. coli* [uropathogenic *E. coli*, UPEC]). Some isolates, *E. coli* O18:K1:H7, are recognized as having the potential to cause both invasive neonatal diseases and urinary tract infections (UTI; Johnson et al., 2001a; Johnson et al., 2001b).

UPEC are a heterogeneous group of clones (Donnenberg and Welch, 1996). Within the UPEC grouping are cystitis, pyelonephritis and urosepsis isolates. These strains are the principal causes of morbidity and mortality from either community or hospital-acquired *E. coli* infections. Approximately 60% of adult women will have a UTI in their lifetimes (Kunin, 1994). As much as 90% of all community-acquired UTIs and greater than 30% of the hospital-acquired UTIs are caused by *E. coli* (Haley et al., 1985). There have been reports of community-wide outbreaks of UTIs by multidrug resistant UPEC clones (Manges et al., 2001).

UPEC strains isolated from women with pyelonephritis, but who have no underlying medical complications, often possess specific O serotypes (O1, O2, O4, O6, O7, O18 and O75; Orskov and Orskov, 1983a; Orskov and Orskov, 1983b; Orskov and Orskov, 1985; Johnson et al., 1987; Wold et al., 1992). What further suggests that these *E. coli* strains are extraordinary is that they are especially capable of invading the bloodstream (Johnson et al., 1987; Johnson et al., 1988; Johnson, 1991a; Johnson et al., 1991b; Johnson et al., 1994). Many of the known or putative virulence factors for these strains are not shared with

common fecal *E. coli* strains. Examples of such factors are adhesins (e.g., Pap, Sfa, and Dra), hemolysin (Hly), cytotoxic necrotizing factor-1 (CNF-1), and the aerobactin (Aer) iron-sequestration systems (reviewed by Donnenberg and Welch, 1996). Recently, a member of the autotransporter protein family, Sat, has been demonstrated to be a cytotoxin of uroepithelial cells (Guyer et al., 2000). There are additional factors that are common to all *E. coli* that are critical for pathogenesis of extraintestinal disease. The principal factors are lipopolysaccharide, capsule production, and type 1 pili. The type 1 pili appear to play a particularly critical role in the initial colonization of the bladder (Kisielius et al., 1989; Connell et al., 1996; Langermann et al., 1997; Lim et al., 1998; Struve and Krogfelt, 1999). The type 1 pili have recently been shown to mediate cellular invasion of cultured urinary epithelial cells (Mulvey et al., 1998). It is suggested that intracellular cellular invasion leads to persistent infections of the urinary tract by successive rounds of intracellular infection, multiplication, release and reinfection of superficial, as well as deeper bladder epithelial layers (Mulvey et al., 2001). Currently no information is available about genes other than those for type 1 pili that are needed for cellular invasion.

The first described pathogenicity islands were found to encode the non-type 1 adhesins (e.g., pap, sfa, and dra), toxins (e.g., Hly, CNF1 and Sat), and iron-sequestration systems (e.g., aerobactin; Knapp et al., 1986; Hacker et al., 1990; Blum et al., 1994; Blum et al., 1995). The chromosomal endpoints of these UPEC islands are associated with specific tRNA loci *leuX*, *selC*, *pheV* and *pheU*. Often there are phage integrase-like genes present on one end of the islands. This has led to a common perception that nonpathogenic organisms become pathogens by the acquisition of these virulence genes en bloc via prophages that use the tRNA genes as attachment sites. Comparison of genome sequences of three different *E. coli* strains indicates in excess of 300 unique loci, which appear as insertions or substitutions along the length of these genomes. Clearly there is a subset 10–13 tRNA gene loci where genetic differences among the strains occur uniformly (e.g., *selC*, *pheV* and *leuX*). Therefore, phages probably participated in their acquisition and evolution. There are, however, many more sites where the genomes differ and it is unclear what genetic mechanisms lead to these differences.

MENINGITIS-ASSOCIATED *E. COLI* Along with Group B streptococci, meningitis-associated *E. coli* (MAEC) are the most common causes of neonatal meningitis, a severe disease with a high mortality rate and possible long-term neurologi-

cal problems in survivors (Unhanand et al., 1993; Stoll et al., 2002). There are a limited number of *E. coli* serotypes associated with this disease, but greater than 80% of the strains express K1 capsule (Robbins et al., 1974; Sarff et al., 1975). It is generally thought that the newborn acquires the K1 strain from its mother during passage through the birth canal. The strain then progressively invades the bloodstream and subsequently crosses endothelial surfaces into the brain. The K1 capsule is a critical determinant in invasion across the blood-brain barrier. In a rat pup model, the capsule was proven to be necessary for survival in the meninges (Hoffman et al., 1999). S-fimbriae enable K1 isolates to adhere to brain microvascular endothelium (Parkkinen et al., 1988). Several genes, *ibeA*, *ibeB*, *ibeC*, *cnf-1* and *aslA*, are required for endothelial cell invasion (Prasadarao et al., 1999; Badger et al., 2000a; Khan et al., 2002). Also common to most MAEC isolates is a 100-kb plasmid that confers increased virulence (Mercer et al., 1984; Badger et al., 2000b). The best-characterized MAEC isolate is RS218, which possesses that classic O18:K1:H7 serotype. Its genome sequence has been determined, although not presented in a published form as of the end of 2004 (see the <http://www.genome.wisc.edu/sequencing/rs218.htm> [E. coli genome project]). Preliminary studies indicate that like the other *E. coli* pathotypes, the K-12, EHEC or UPEC genomes do not contain a significant number of genes unique to RS218. In a genomic comparison of RS218 to K-12, at least 500 kb of DNA are unique to RS218 (Rode et al., 1999; Bonacorsi et al., 2000). See Table 1 for *E. coli* reference sources on the Internet.

The Genus *Edwardsiella*

SHARON L. ABBOTT AND J. MICHAEL JANDA

Taxonomy

In 1965, Ewing and colleagues proposed the creation of a new species, *Edwardsiella tarda*, to house a collection of 37 strains that were primarily of fecal origin. These strains, extensively studied at the United States Centers for Disease Control and Prevention (CDC) since 1959 and referred to as “bacterium 1483–59,” were sufficiently distinct biochemically from other taxa within the family Enterobacteriaceae to warrant this proposal. Simultaneously, a Japanese group (Sakazaki et al., 1965) had been independently studying a collection of 256 Japanese cultures, mostly from snakes, with similar, though not identical, biochemical properties to bacterium 1483–59 (Farmer and McWhorter, 1984). These reptilian isolates were given the vernacular name “Asakusa Group,” a reference to the place from which they were originally isolated. Others, most notably King and Adler (1964) and Rakovskí and Aldov (1965), described the “Bartholomew Group,” which was a collection of yet other unidentified Enterobacteriaceae strains isolated from diarrheal stools with properties similar to *E. tarda*. This group of organisms took its name from the county hospital in Columbus, Indiana, where the first fecal isolate had been recovered.

Don Brenner at the Walter Reed Army Institute of Research, in a DNA hybridization study (Brenner et al., 1974), tested the validity of *E. tarda* as a new taxon within the Enterobacteriaceae and its relationship to the other phenotypically similar groups (Asakusa, Bartholomew). Polynucleotide sequence data indicated 1) the relatedness of *E. tarda* to *Escherichia coli* K-12 was only 20%, and 2) all 20 strains of *E. tarda*, isolated from diverse sources and geographic locales, formed a single highly related (88% at 60°C) hybridization group. Furthermore, by DNA-DNA hybridization, members of the bacterium 1483–59, and the groups Asakusa and Bartholomew were found to belong to the same species, *E. tarda* (Table 1). These studies conclusively established the legitimacy of the genus and species, *Edwardsiella tarda*, and the relationship

between this taxon and the Asakusa and Bartholomew groups.

In 1975, Sakazaki and Tamura challenged the species name “*tarda*” over the epithet “anguillimortiferum” based upon an earlier published species designation, *Paracolobactrum anguillimortiferum*, proposed in 1962 by Hoshina, for an organism recovered from eels. This bacterium had biochemical properties identical to those of *E. tarda* in tests performed in common. However, Hoshina (1962) failed to designate a type strain, and the original culture of *P. anguillimortiferum* was lost in the intervening years. Because “anguillimortiferum” was validly published first and had taxonomic priority over “*tarda*,” Sakazaki and Tamura (1975) proposed the name *E. anguillimortifera* (Hoshina) comb. nov. to replace the illegitimate combination *E. tarda*. Invoking the first principle of the *International Code of Nomenclature of Bacteria*, which calls for preserving nomenclatural stability and avoiding confusion, Farmer et al. (1976) subsequently argued for keeping the more widely used *tarda* over *anguillimortiferum*. Although an opinion was never formally rendered, the situation was resolved by the publication of the approved list of bacterial names in January, 1980 (Skerman et al., 1980). Although both *E. tarda* and *E. anguillimortifera* (p. 292) appeared on the approved list of bacterial names as objective synonyms, *E. tarda* was designated the type species. Ultimately, Sakazaki and Tamura (1991) recommended that the name *E. tarda* be retained based upon its common usage in most scientific reports.

The genus *Edwardsiella*, named in 1965 after P.R. Edwards (a CDC microbiologist) to honor his numerous contributions to the field of enteric bacteriology, contained only a single species until 1980 (Sakazaki and Tamura, 1991). Then in rapid succession two new species were added. First, Grimont et al. (1980) published data on a group of malonate- and D-mannitol-positive strains recovered from reptiles and birds, which, based upon DNA-DNA reassociation kinetics, constituted a new species. The name *E. hoshinae* was proposed for this new group, in honor of the

Table 1. Reassociation kinetics of *E. tarda* strains to *E. tarda* (CDC 3592-64).

CDC strain no.	Descriptor	Relative binding (%)		Divergence (%)
		60°C	75°C	
3592-64	Asakusa group, Japan	100	100	NT
5497-61	Asakusa group, Japan	85	84	0.1
1483-59	<i>E. tarda</i> type strain, Kentucky	91	NT	0.1
1795-62	Original Bartholomew strain	84	82	0.3

CDC, US Centers for Disease Control and Prevention; NT = not tested.

Data from Brenner et al. (1974).

Japanese bacteriologist Toshikazu Hoshina; CIP 78-56 (ATCC 33379) was designated the type strain. To date, the report by Grimont et al. (1980) is the only publication in the literature on this *Edwardsiella* species. Hawke et al. (1981) described a third *Edwardsiella* species, *E. ictaluri*, from isolates of channel (*Ictalurus punctatus*) and white (*Ictalurus catus*) catfish. Five of 13 *E. ictaluri* were 81–97% related to the type strain ATCC 33202 (CDC 1976–78) in DNA-DNA reassociation studies, whereas *E. tarda* and other members of the Enterobacteriaceae were only 56–61% and 6–41% related to *E. ictaluri*, respectively. Results of multilocus enzyme (isozyme) electrophoresis conducted on 33 isolates for 23 loci indicate *E. ictaluri* is an extremely homogeneous species with a mean genetic diversity of 0.033 and an average of 1.304 electromorphs per loci (Starliper et al., 1988). Currently then, the genus *Edwardsiella* has three species with taxonomic standing. The type species for the genus is *E. tarda* (type strain ATCC 15947) and the G+C content of *Edwardsiella* species is 53–59 mol% (Sakazaki and Tamura, 1991).

Phylogeny

The genus *Edwardsiella* is a member of the Enterobacteriaceae based upon biochemical and physiologic characteristics (Brenner, 1984), the presence of the enterobacterial common antigen (Mikeli and Mayer, 1976), and DNA relatedness, albeit distant, to core genera in this family (including *Escherichia*; Brenner, 1977). Thus by definition, *Edwardsiella* is a member of subgroup 3 of the γ subclass of the class *Proteobacteria* (superfamily I), formerly known as purple bacteria (Woese et al., 1985; Stackebrandt et al., 1988; Logan, 1994).

It is somewhat difficult to find the correct phylogenetic position of *Edwardsiella* within the family Enterobacteriaceae, which has been overclassified for medical purposes and has roughly the equivalent genetic diversity of a single genus such as *Bacillus* (Ahmad et al., 1990; Logan, 1994). This means that phylogenetic trees constructed from 16S rRNA sequence analysis and

DNA-rRNA hybridization data are not always useful in determining the correct evolutionary picture at the genus and species level (Logan, 1994). In addition, 16S rRNA and signature sequences for *Edwardsiella* and *E. tarda* have not been formally published (Stackebrandt et al., 1988) and many evolutionary trees do not contain *Edwardsiella* (MacDonell et al., 1986; Ahmad et al., 1990; Logan, 1994).

At the DNA level, the genus *Edwardsiella* is only ~20% related to *E. coli* and to other core genera of the family Enterobacteriaceae including *Salmonella*, *Shigella* and *Citrobacter* (Brenner, 1977). In investigations conducted by Brenner et al. (1974), the highest degree of DNA relatedness between *E. tarda* CDC 3592-64 and other genera in this family was noted with *Hafnia* (29%) and *Serratia* (28%). The large evolutionary distance between *Edwardsiella* and these core genera is further supported by molecular analysis of housekeeping genes.

The phylogenetic branching of biochemical pathways can be used to indicate points of divergence among various prokaryotic microorganisms; this is particularly true for amino acid biosynthesis. For instance, for genes regulating aromatic amino acid biosynthesis (e.g., of tryptophan), all enterobacteria have a T protein (chorismate mutase-cyclohexadienyl dehydrogenase) and three regulatory isozymes of 3-deoxy-D-arabino-heptulosonate 7-phosphate synthase. However, they differ in respect to the presence of an anthranilate synthetase: anthranilate 5-phosphoribosylpyrophosphate phosphoribosyltransferase gene fusion (*trpG-trpD*), the presence or absence of cyclohexadienyl dehydratase and of a chorismate mutase species free of any known association (Ahmad and Jensen, 1988; Ahmad et al., 1990). A phylogenetic tree based upon 16S rRNA data and biochemical character states (i.e., aromatic amino acids) identifies three enteroclusters, the third of which contains the genera *Edwardsiella*, *Cedecea*, *Kluyvera*, *Hafnia*, *Yersinia*, *Proteus*, *Providencia* and *Morganella* (Ahmad et al., 1990). In *E. coli*, the leader regions of the *ilvGMEDA* operon, which controls expression of branched-chain amino acids (isoleucine, leucine and valine), is similar to the

ilvG region of other enteric bacteria (Harms et al., 1985; Williamson and Jackson, 1987). The *ilv* leader region sequence of *Salmonella* and *Klebsiella* and that of *E. coli* have >96% homology (Harms et al., 1985). In contrast, the sequence diversity between either *Edwardsiella tarda* or *Serratia marcescens* and *E. coli* is 25–29%. The tRNA^{Leu} sequence of *E. coli* is homologous with the leader peptide-coding region of the *ilvGMDA* leader transcript of *E. coli*, *S. typhimurium* and *Klebsiella aerogenes* but not with that of *Serratia marcescens* or *E. tarda* (Williamson and Jackson, 1987).

Results reported in the analysis of amino acid biosynthesis genes are similar to those reported in other housekeeping genes. TonB homologues are involved in the transport of ferric siderophores and are present in most enterobacteria excluding *Morganella*. However, unlike most core enterobacteria (*E. coli*, *Shigella* and *Citrobacter*), *Edwardsiella tarda* only reacts weakly with α -TonB polyclonal antiserum and not at all with several TonB-specific monoclonal antibodies (Larsen et al., 1996). In yet another example, cloned genes from two *E. coli* catalases (*katG*, *katE*) used as probes in Southern hybridization assays failed to detect analogous sequences in other Enterobacteriaceae including *E. tarda*, *Proteus mirabilis*, *S. marcescens* and *Erwinia carotovora* isolates (Switala et al., 1990). Cumulatively, these results suggest a distant phylogenetic relationship between edwardsiellae and core members of the Enterobacteriaceae such as *E. coli*.

No formal 16S rRNA (small-subunit) phylogenetic trees of the family Enterobacteriaceae that include the genus *Edwardsiella* have been published (Stackebrandt et al., 1988); the same is true for 5S rRNA cluster analysis (MacDonell et al., 1986). However, when 16S rRNA sequences for all three *Edwardsiella* species present in the MicroSeq database (Applied Biosystems and Applera Corporation Business) were used to conduct a BLAST search (the results of which provide the top 20 related sequences ordered by minimum distance) and then subjected to a phylogenetic analysis based upon the neighbor-joining (NJ) method (Saitou and Nei, 1987), the closest neighbors in the family Enterobacteriaceae to the genus *Edwardsiella* were found to be *Trabulsiella guamensis* and *Enterobacter sakazakii* (Fig. 1).

The legitimacy of each *Edwardsiella* species, as determined by small-subunit rRNA sequences, is also supported by phylogenetic analysis of the superoxide dismutase (*sodB*) gene, which has two clusters (Yamada and Wakabayashi, 1999). Cluster 1 contains *E. ictaluri* and cluster 2 contains *E. hoshinae* and typical *E. tarda* strains.

Fig. 1. Phylogenetic placement of *E. tarda* using 16S rDNA sequences analyzed by the neighbor-joining method. (From MicroSeq™ Analysis Software, 1999, with permission.)

Habitat

Unfortunately, no extensive surveys on the natural habitat(s) of *Edwardsiella* species have ever been undertaken. Collective evidence, however, indicates freshwater environments and animals that have extensive contact with aquatic ecosystems are, most likely, the primary habitat of the edwardsiellae (Janda and Abbott, 1993). This hypothesis is supported by the low carriage rate of *E. tarda* in the human gastrointestinal tract (Janda and Abbott, 1993) and numerous reports describing the isolation of *Edwardsiella* from mammals, birds, reptiles, amphibians, and marine and freshwater life (Janda and Abbott, 1998). More specifically, as noted in Table 2, freshwater fish appear to be the primary habitat for at least two *Edwardsiella* species, *E. tarda* and *E. ictaluri*. *Edwardsiella ictaluri* is almost exclusively associated with ictalurid fish, although this species has on occasion been cultured from non-ictalurid fishes. *Edwardsiella tarda* has a broader host range amongst piscine species (Table 2). Other marine life from which *E. tarda* can occasionally be isolated includes mullet (*Mugil cephalus*), cultured sea bream (*Evynnis japonicus*), seals, sea lions, mussels and clams (Frerichs, 1989; Sakazaki and Tamura, 1991; Janda and Abbott, 1998). Both species also are recovered from environmental samples associated with aquatic ecosystems including pond water and sediment samples (Wyatt et al., 1979; Yamada and Wakabayashi, 1999).

In addition to fish, reptiles and amphibians also are likely reservoirs for *E. tarda* (Table 3). Reptiles found colonized or infected with *E. tarda* include alligators, crocodiles, lizards (e.g.,

Table 2. Isolation of *Edwardsiella* species from fish.

Organism	Common name	Scientific name
<i>E. tarda</i>	Nile tilapia	<i>Oreochromis niloticus</i>
	Ayu	<i>Plecoglossus altivelis</i>
	Japanese flounder	<i>Paralichthys olivaceus</i>
	Japanese eel	<i>Anguilla japonica</i>
	Australian eel	<i>Anguilla reinhardtii</i>

Table 3. Natural reservoirs of edwardsiellae.

Organism	Major reservoir	Incidental hosts
<i>E. tarda</i>	Amphibians	Mammals
	Fish	
	Reptiles	
<i>E. ictaluri</i>	Ictalurid fish	Nonictalurid fish
<i>E. hoshinae</i>	Unknown	Lizards
		Birds

skinks), tortoises, aquatic turtles and snakes, whereas amphibians found colonized include frogs and toads (Sakazaki and Tamura, 1991; Janda and Abbott, 1998). A Russian survey of zoo reptiles found 43% of crocodiles, 36% of snakes, 24% of tortoises, and 18% of lizards carried edwardsiellae (Kalina et al., 1981). Roggen-dorf and Mueller (1976) isolated *E. tarda* from 20% of tortoises, 12% of snakes and 3% of lizards they tested and suggested that tortoises might be a normal habitat for this bacterium. A study conducted on wild animals in Panama found 6% of toads and 5% of snakes harbored *E. tarda* (Kourany et al., 1977). Sharma (1979) found the intestinal tract of 21% of wild toads tested positive for *E. tarda*. Birds from which *E. tarda* has been isolated include bald eagles, blue herons, brown pelicans, gulls, king vultures, loons, ostriches, penguins and sandbill cranes (Janda and Abbott, 1998). After seagulls (*Larus*) were implicated in the contamination of fish in processing plants, Berg and Anderson (1972) hypothesized that birds might disseminate edwardsiellae from natural aquatic ecosystems to other mammals. Much less often, warm-

blooded mammals such as cattle, dogs, monkeys, opossums, panthers, pigs, rats and skunks have been found to transiently harbor *E. tarda* (Kourany et al., 1977; Sakazaki and Tamura, 1991; Janda and Abbott, 1998).

Little is known regarding the habitat of *E. hoshinae*. In the only publication on this species, *E. hoshinae* was isolated from three monitor lizards (*Varanus* sp.), two puffins (*Fratercula artica*), an unspecified lizard, a flamingo (*Phoenicopterus ruber*), and water (Grimont et al., 1980).

Isolation

Although virtually indistinguishable from H₂S-positive *Salmonella* on most enteric plating media, *E. tarda* can be readily isolated from humans and animals on enteric plating media containing fermentable substrates, such as lactose and sucrose (MacConkey, xylose-lysine-desoxycholate [XLD], Hektoen, *Salmonella-Shigella* [SS] and desoxycholate citrate [DC] agars). Colonies appear colorless and therefore assume the color of the plating medium. On those media that incorporate detectors of H₂S (all of the above listed media except MacConkey), colonies will have a black center indicating H₂S has been produced (Fig. 2).

Biogroup 1 strains of *E. tarda*, which are H₂S-negative and sucrose-positive, will be most easily identified on media containing only lactose (MacConkey, SS and DC agars), and they will not have black centers. Bismuth sulfite and brilliant green agars, both excellent for *Salmonella*

Fig. 2. Colorless colonies of *E. tarda* on *Salmonella-Shigella* (SS) agar showing H₂S-positive centers.

isolation, may inhibit growth of *E. tarda* (Sakazaki and Tamura, 1991). In 1973, Muyembe et al. found intrinsic resistance to colistin among strains of *E. tarda*, thus incorporation of this polypeptide antibiotic into any enteric plating media should enhance the isolation of *E. tarda*. Despite several reports that indicate 10% of *E. tarda* strains are susceptible to colistin (Reinhardt et al., 1985; Waltman and Shotts, 1986a), the addition of this antibiotic to several novel media has (in fact) enhanced the isolation of *Edwardsiella*. Lindquist (1991) created a new isolation medium, *Edwardsiella tarda* (ET) agar, by adding colistin to MacConkey agar base.

ET Medium for Isolation of *E. tarda* (Lindquist, 1991)

MacConkey agar base	40.0 g
Yeast extract	1.0 g
Agar	4.5 g
Distilled water	100.0 ml

Autoclave and then cool; add the following two filter-sterilized solutions:

Glucose	2.0 g
Sucrose	5.0 g
Mannitol	5.0 g
Xylose	5.0 g
L-Lysine	10.0 g
Sodium thiosulfate	6.8 g
Ferric ammonium sulfate	0.8 g
Distilled water	100.0 ml
Colistin (1 mg/ml)	10.0 ml

Colonies of *E. tarda* appear clear to whitish with black centers after incubation at 37°C overnight. *Edwardsiella tarda* biogroup 1 strains, which ferment sucrose, grow on this medium as red colonies with black centers. Lindquist (1991) recovered *E. tarda* from 30.2% (16/53) of water samples on ET agar. All H₂S-positive colonies were identified as *E. tarda*, whereas none of the H₂S-negative colonies were *E. tarda*.

Inasmuch as *E. hoshinae* (like *E. tarda* biogroup 1 strains) ferments sucrose, MacConkey, SS and DC agars are the most suitable enteric plating media for isolation. Colonies will be small (1–2 mm); *E. hoshinae* strains will grow at either 30° or 37°C (Grimont et al., 1980). *Edwardsiella ictaluri* does not ferment lactose or sucrose, and despite its inability to produce H₂S, it should be easily recognizable on enteric plating media. However, because it is slow growing, even at preferred temperatures of 25° to 30°C, requiring 48 to 72 h to form 1–2 mm colonies (Sakazaki and Tamura, 1991), it is often overgrown by other flora. Shotts and Waltman (1990) devised a selective medium called *E. ictaluri* medium (EIM) to specifically address this problem.

EIM of Waltman and Shotts (1989)

Bacto-peptone	10.00 g
Yeast extract	10.00 g
Agar	17.00 g
Phenylalanine	1.25 g
Ferric ammonium sulfate	1.20 g
Sodium chloride	5.00 g
Brom thymol blue	0.03 g
Bile salts	0.10 g
Distilled water	100.0 ml

Adjust the pH to 7.0–7.2, autoclave at 121°C for 15 minutes. Cool and add 10.0 ml of a filter-sterilized solution containing 3.5 g of mannitol and 10 mg of colistin just before pouring plates.

On EIM, *E. ictaluri* and *E. tarda* produce small (1 mm) green, translucent colonies after 48 hours, which are easily distinguishable from the few environmental flora that are not inhibited. Unfortunately, swarming *Proteus* species can still grow on this medium but their growth would be uninhibited on other media as well. Use of EIM agar has been found to enhance the isolation of *E. ictaluri* in channel catfish coinfecting with *Aeromonas hydrophila*, an organism that otherwise would easily overgrow *E. ictaluri* (Earlix et al., 1996).

Edwardsiella can be recovered from all enteric enrichment broths including selenite cysteine, Hajna's Gram-negative (GN) and tetrathionate broths. Van Damme and Vandepitte (1980) found that the recovery of *E. tarda* was better in tetrathionate broth without the addition of iodine. Alternative enrichment broths that have been used for edwardsiellae include double-strength SS broth (Wyatt et al., 1979) and strontium chloride B broth (Iveson, 1973).

Strontium Chloride B Broth (Iveson, 1973)

Bacto-peptone	0.5 g
Sodium chloride	0.8 g
Potassium dihydrogen phosphate	0.1 g
Strontium chloride (60% w/v)	6.0 ml
Distilled water	100.0 ml

Sterilize by steaming 30 minutes; adjust pH to 5.0–5.5.

Asymptomatic channel catfish carrying *E. ictaluri* that appear normal and are negative by conventional culture techniques can spread enteric septicemia to susceptible catfish populations. To detect *E. ictaluri* in these situations, an enzyme-linked immunosorbent assay (ELISA) using anti-*E. ictaluri* hybridoma supernatant 9G4-D9 antibody was developed (Earlix et al., 1996). Homogenized catfish tissue, treated with 0.5% Triton-X, was filtered onto a 0.45 micron pore nitrocellulose filter, which was subsequently placed on EIM agar and incubated 24 h at 25°C before ELISA testing.

Identification

Edwardsiella tarda is an easily recognizable member of the Enterobacteriaceae. It produces H₂S, decarboxylates lysine, produces indole from tryptophan (Fig. 3), and as indicated by its species designation *tarda*, does not ferment any carbohydrate or sugar alcohols except glucose, maltose and occasionally glycerol.

Biochemicals that separate *E. tarda* from other H₂S-positive genera of the Enterobacteriaceae, many of which are associated with water habitats, can be found in Table 4.

Biogroup 1 strains of *E. tarda* ferment sucrose, mannitol and arabinose in addition to maltose but are H₂S-negative. Two recent publications (Walton et al., 1993; Leung, 1996) have described sucrose-positive strains of *E. tarda* that are H₂S-positive and do not ferment mannitol or arabinose, and therefore, do not belong to biogroup 1. It remains to be seen if these strains are a new species or a second biogroup of *E. tarda*.

Because *E. tarda* biogroup 1 strains, *E. hoshinae* and *E. ictaluri* all lack the ability to produce

H₂S, they may be difficult to separate from other inactive genera within the Enterobacteriaceae. Their ability to decarboxylate lysine and ornithine and the inability to utilize citrate or deaminate phenylalanine are helpful distinguishing characteristics. They also may easily be confused with inactive strains of *E. coli*; however, the colistin or polymyxin B resistance of *Edwardsiella* can be used to separate them from inactive strains of *E. coli*. *Edwardsiella ictaluri* cultures should be incubated at 25°C, the temperature at which they have increased biochemical activity. For instance, motility that is present at 25°C may be delayed 3 to 5 days, or be negative at 37°C. Early descriptions of this organism by Hawke (1979) indicated gas was not produced from

Fig. 3. Typical reactions for *E. tarda* in triple sugar iron (TSI), lysine iron (LIA), and motility-indole-ornithine (MIO) agars. Both TSI and LIA show H₂S production (blackening); the purple color in the butts of the LIA and MIO tubes indicate lysine and ornithine were decarboxylated. Motility is exhibited as turbidity throughout the MIO tube and the pink color in the Kovac's reagent at the top indicates indole production.

glucose at 37°C; however, Waltman and Shotts (1986a) found diminished gas production in 54% of their strains at 37°C. *Edwardsiella* species are easily differentiated from each other by a few simple biochemical reactions (Table 5).

Biochemical characteristics uniformly positive or negative for all *Edwardsiella* are included in Table 6. Additionally, tests for which some variability has been noted amongst species are also listed.

Both *E. tarda* and *E. ictaluri* lack proteases, lipases, esterases, pectinase, collagenase, alginate, chitinase and hyaluronidase. However, 100% and 56% of 100 strains of both *E. ictaluri* and *E. tarda*, respectively, degraded chondroitin sulfate (Waltman et al., 1986b; Waltman et al., 1986c). Information regarding the production of these enzymes was not found for *E. hoshinae*.

Serotyping

Because *E. tarda* strains are biochemically homogeneous and relatively inactive, there are no biotyping systems. Consequently, serotyping has been the method used to epidemiologically define strains. Two serotyping schemes for *E. tarda*, developed independently in Japan and the United States, were merged in 1988 to form a single international scheme (Tamura et al., 1988). The scheme is now comprised of 61 somatic (O) and 45 flagellar (H) antigens, and serotyping is performed as described by Sakazaki (1984). Briefly, O antigens are determined by slide agglutination assay using equal amounts of boiled saline suspension from an overnight agar slant culture and working dilution of O antisera. The H antigens are identified by tube agglu-

ination using an overnight culture grown in brain heart infusion broth to which an equal volume of saline with 0.2% thimerosal has been added. Unlike *Salmonella*'s, *E. tarda*'s flagellar antigens are monophasic and do not occur in complexes. Serotyping is now performed only at the National Institute of Health, Tokyo, Japan (Tamura et al., 1988). There are no serotyping schemes for *E. ictaluri* and *E. hoshinae*.

Strains of *Edwardsiella* also may be epidemiologically typed by plasmid analysis (Reger et al., 1993). The utility of ribotyping, PCR typing, or pulsed-field gel electrophoresis for classifying these strains has not been reported.

Antimicrobial Susceptibility

All species of *Edwardsiella* are uniformly susceptible to all antibiotics or to all β -lactam

antibiotic- β -lactamase inhibitor combinations (Table 7) that are used to treat gastrointestinal and systemic infections (Reinhardt et al., 1985; Reger et al., 1993; Clark et al., 1991). Interestingly, this includes the β -lactam antibiotics even though all isolates of *E. tarda* tested to date have been found to produce β -lactamases. None of thirteen *E. hoshinae* or ten *E. ictaluri* strains tested by Reger et al. (1993) possessed β -lactamases. Ninety percent of *E. tarda* strains (Waltman and Shotts, 1986a) and all *E. ictaluri* strains studied by Shotts and Waltman (1990) are resistant to colistin or polymyxin B, whereas *E. hoshinae* are variable in their susceptibility to these agents (Sakazaki and Tamura, 1991). Because of their slow-growth, *E. ictaluri* require 48 h of incubation at 25°C for broth dilution (Reger et al., 1993) and disk diffusion (Sakazaki and Tamura, 1991) testing. The use of only four disks per 150-mm Mueller-Hinton agar plate is

recommended because the zones of growth inhibition are large.

Genetics

Plasmids

Extrachromosomal elements have been detected in all three *Edwardsiella* species. Virtually all *E. ictaluri* are known to carry small plasmids <10 kb in size. Lobb and Rhoades (1987) found cryptic plasmids of 5.7 and 4.9 kb in all 18 *E. ictaluri* strains recovered from channel catfish, although their relative mobility in agarose gels and their restriction maps indicated the plasmids were not closely related to each other. Common endonucleases found to cleave both plasmids included *EcoRI*, *BglII*, and *PstI*. Subsequent studies have indicated that most *E. ictaluri* strains, regardless of origin, contain classes of homologous plasmids of similar, but not identical, sizes that are genetically related (Reid and Boyle, 1989; Lobb et al., 1993). These plasmid classes include a 4.0 to 4.7 kb plasmid and a 5.6 kb plasmid (Reger et al., 1993). This suggests that these cryptic plasmids are extremely stable and highly conserved in almost all *E. ictaluri* isolates. One isolate of *E. ictaluri* from a green knife fish was found to contain four plasmids ranging in size from 3.1 to 6.0 kb (Lobb et al., 1993). Minor variations in plasmid carriage, other than the two major classes, have been noted in strains recovered from non-ictalurid fish (Reid and Boyle, 1989).

In contrast to the small-size plasmids detected in *E. ictaluri* strains, much larger extrachromosomal elements have been isolated from both *E. tarda* and *E. hoshinae* isolates. Plasmids in these two species range in molecular mass from 2 to 120 Mda, and unlike in *E. ictaluri*, plasmid carriage appears to vary significantly from strain to strain (Janda et al., 1991a). Reger et al. (1993) found that 6 of 13 *E. hoshinae* strains contained a single plasmid of ~54 kb, while approximately half of the *E. tarda* strains tested carried plasmids ranging from 5.0 to 76 kb. Functions for these plasmids have not been identified to date. The R plasmids encoding resistance to both tetracycline and sulfonamide, or to the combination of chloramphenicol, tetracycline and sulfonamide have been detected in strains of *E. tarda* recovered from eel ponds (Aoki, 1988). These R plasmids have been classified into incompatibility groups A–C.

Transformation

Edwardsiella species have been transformed with both plasmids and transposons. *Escherichia coli* can transfer R plasmids to *Edwardsiella icta-*

luri strains at frequencies ranging from 10^{-3} to $10^{-6.5}$ (Waltman et al., 1989). Resistance markers transferred on a ~40 MDa plasmid included tetracycline, chloramphenicol, kanamycin, ampicillin and trimethoprim-sulfamethoxazole. Similarly, one strain of *E. ictaluri* was shown to be capable of transferring R plasmids to both *E. coli* and *Yersinia ruckeri* at frequencies approaching 10^{-4} . *Edwardsiella tarda* strains have been stably transformed with plasmids encoding green or blue fluorescent protein (Ling et al., 2000). Strauss et al. (1997) was able to mutagenize a strain of *E. tarda* by transformation with a plasmid containing an ampicillin-resistance gene and a transposon Tn5 derivative with a tetracycline resistance gene. However, Strauss noted that the transformation frequency of *E. tarda* was ~1,000-fold less than that of *E. coli*.

Ecology

The microecology of *Edwardsiella* species, and in particular *E. tarda*, is poorly understood. At present it is unclear whether most *Edwardsiella* species are obligate pathogens or can thrive in environments outside of their primary hosts (Thune et al., 1993). Data collected on known sources of *E. tarda* suggest that this species does not exist as a free-living microorganism in natural waters. Most aquatic isolates of *E. tarda* originate from pond or culture water inhabited by various fish, eels, amphibians, etc., that harbor edwardsiellae in their digestive tracts or on their exterior surfaces. Warmer temperatures during summer months are known to increase incidence of recovery of *E. tarda* from catfish pond water and mud samples (Wyatt et al., 1979). In their study, King and Shotts (1988) found that strains of *E. tarda* survived poorly in saline suspensions; viable numbers declined by >100-fold within 72 h. However, cocultivation of *E. tarda* with a ciliated protozoan, *Tetrahymena pyriformis*, yielded a 2–3 fold increase in bacterial numbers over the initial inoculum during the same time interval (King and Shotts, 1988). This suggests that persistence of *E. tarda* in freshwater environments may be facilitated by the ingestion of edwardsiellae by ciliated protozoans, leading to subsequent intracellular multiplication of bacteria within the host. Thus protozoa may play an intermediary role in the *E. tarda* colonization of other animals within aquatic ecosystems. The ecologic distribution of *E. ictaluri* appears restricted probably because it is almost exclusively an obligate pathogen of ictalurid fish (Hawke et al., 1981) and has an optimal lower growth temperature of 25°C (see Physiology section). Studies conducted with channel catfish fingerlings indicate that mortality increases in *E.*

ictaluri-infected fish in water temperatures ranging from 23 to 28°C (Francis-Floyd et al., 1987). The fact that *E. hoshinae* has not been isolated from any sources since its initial taxonomic description indicates that either this species has an extremely limited ecologic distribution or is uniquely adapted to an as yet unknown host.

Epidemiology

Fish Diseases

Factors regulating the infectivity of *Edwardsiella* in fish are probably similar, if not identical, to those associated with piscine diseases caused by other aquatic pathogens such as *Aeromonas*. It is well recognized that, for both *E. ictaluri*- and *E. tarda*-associated infections, morbidity and mortality increases as water temperatures rise (Francis-Floyd et al., 1987; Greenlees et al., 1998). Other factors that may increase the incidence of infections include stress and organic load (Greenlees et al., 1998).

Human Illnesses

Although human infection caused by *E. tarda* is a relatively infrequent event, there is surprisingly good information in the literature collected from individual case reports on risk factors associated with edwardsiellosis. Most cases of gastroenteri-

tis are associated with handling or consumption of raw or improperly cooked fish. Contact with unusual or exotic pets, although less common, is also a source of infection. Most pet-related cases of *Edwardsiella gastroenteritis* involved contact with or handling turtles (Marsh and Gorbach, 1982; Nagel et al., 1982). However, other pets, including reptiles, have been implicated in transmission (Fang et al., 1991). Cases of *E. tarda* septicemia most often occur in immunocompromised persons. The most common underlying risk factor in such individuals is hepatic cirrhosis; ~50% of persons developing *E. tarda* bacteremia have liver-related disease such as hepatosplenomegaly, icterus or hepatoma (Janda and Abbott, 1993). Wound infections typically result from penetrating or blunt trauma to mucosal surfaces exposed to either aquatic environments or inhabitants. Table 8 lists the main risk factors associated with *E. tarda* infections.

Disease Manifestations

Fish Diseases

As noted in Table 9, both *E. ictaluri* and *E. tarda* are important pathogens of fish (Frerichs, 1985; Thune et al., 1993). The causative agent of enteric septicemia of catfish (ESC; Fig. 4), *E. ictaluri* is responsible for enormous economic losses to the channel catfish industry, the largest aquaculture business in the United States (Hawke et al., 1981). A 1988 fish mortality summary for catfish listed *E. ictaluri* (n = 1,169) as the leading cause of death, accounting for 48% of all cases reported (Durborow et al., 1991). Typically occurring in the spring to early fall when water temperatures are between 22–28°C (Thune et al., 1993), ESC has two forms, either a rapidly fatal, acute gastrointestinal septicemia or a chronic condition typified by a “hole in the head” lesion, associated with a lower mortality rate (Thune et al., 1993).

Characteristics of ESC include gross petechial hemorrhagic lesions occurring around the throat and mouth, cutaneous lesions on the lateral body surface, and pale gills (Hawke, 1979). Internally,

Table 8. Risk factors associated with *Edwardsiella* infections.

Disease or condition	Risk factor or epidemiologic association
Gastroenteritis	Consumption of raw or undercooked fish Contact with exotic pets
Septicemia	Underlying liver disease Preceding episode of <i>E. tarda</i> diarrhea Occupational (zoo) or environmental exposure
Wound infections	Catfish-related injuries Recreational/occupational activities related to aquatic exposure (e.g., swimming, fishing)

fish suffering from ESC exhibit renal hypertrophy, hemorrhage and necrosis in the liver, bloody ascites fluid, and widespread petechial hemorrhages in inner walls of the visceral cavity (Hawke, 1979). The "hole-in-the-head" lesion occurs on the frontal bone of the skull of channel catfish (Fig. 5), and involves erosion of the skin and muscle overlying the skull (Francis-Floyd et al., 1987). *Edwardsiella tarda* also is recognized as an occasional pathogen of channel catfish, largemouth bass, and several other freshwater species including rainbow trout (Meyer and Bulloch, 1973; Amandi et al., 1982; Francis-Floyd et al., 1993; Reddacliff et al., 1996).

In catfish infected with *E. tarda*, Meyer and Bulloch (1973) described "emphysematous putrefactive disease" as cutaneous lesions on the

lateral surfaces of fish that develop into deep cavitory abscesses containing gas and necrotic material. In the Chesapeake Bay in 1994, a large *E. tarda*-associated epizootic in wild striped bass occurred that was typified by numerous irregular, hemorrhagic ulcers on the body and fins of the fish (Baya et al., 1997). Wild-type (classical) *E. tarda* was recovered in pure culture from the internal organs of striped bass including spleen, liver, and pronephroi and coelomic fluids (Baya et al., 1997). The role of *E. tarda* as an opportunistic pathogen in diseased chinook salmon (*Oncorhynchus tshawytscha*) and steelhead trout in the Pacific Northwest (Amandi et al., 1982) was also suspected.

Diseases of Other Animals

Particularly in zoological parks, *E. tarda* has been known to cause sporadic infections in a variety of animals. In 1985, an outbreak of enteritis in Rockhopper penguins, in which eight birds died, was attributed to *E. tarda* (Cook and Tappe, 1985). Histologic analysis of the small intestine of four of these birds revealed segmental-to-diffuse enteritis with villous atrophy, goblet-cell hyperplasia, and lymphoplasmacytic infiltrates in the lamina propria. Necropsy specimens on four of five penguins submitted for bacteriologic analysis grew *E. tarda*. A retrospective review of mortality between 1973–83 at the Detroit zoo found that bacteria caused ~37% of reptilian deaths (Kaneene et al., 1985). *Edwardsiella* was one of five bacterial genera (that also included *Aeromonas*, *Salmonella*, *Proteus* and *Pseudomonas*) responsible for most of the mortality that occurred primarily in iguanas and snakes.

Human Infections

An uncommon human pathogen, *E. tarda* is the only species in its genus known to cause disease in man (Janda and Abbott, 1993). Categories of illnesses associated with *E. tarda* infection, in decreasing order of frequency, include gastroenteritis, septicemia, wound infections, hepatic abscesses and miscellaneous illnesses (Janda and Abbott, 1993).

Gastroenteritis, the most common *E. tarda*-associated disease in humans, has a worldwide distribution, although higher infection rates appear to occur in tropical and subtropical climates (Gilman et al., 1971; Kourany et al., 1971; Ovartharnporn et al., 1986). Reasons for this demographic association include different dietary habits (high consumption of fish, often raw), increased fishing-related activities, or drinking water from freshwater sources that are in intimate contact with reptiles and amphibians (Kourany et al., 1977; Van Damme and Vande-

pitte, 1980). Infection rates in symptomatic persons with *E. tarda*-associated diarrhea have ranged from 0.2 to 13.9% in selected studies; carrier rates in these surveys vary from 0 to 5.4% (Janda and Abbott, 1993; Janda and Abbott, 1998). A Panamanian survey conducted between 1965 and 1972 found 1.1% of all non-urban persons were either colonized or infected with *E. tarda*, whereas none of the more than 2,700 urban dwellers surveyed carried this agent (Kourany et al., 1977). Similarly, in a study of the jungle-dwelling Orang Asli (Aborigines) of Western Malaysia, 30% of patients hospitalized with bloody diarrhea had stools containing *E. tarda* (Gilman et al., 1971). However, simultaneous recovery of *Entamoeba histolytica* from the same stools of many of these patients suggested chronic exposure to multiple enteric pathogens in their environment.

Other than a cluster of eight isolates recovered from asymptomatic persons (seven children and one teacher) associated with a Florida day-care center (Desenclos et al., 1990), no outbreak of *E. tarda* diarrhea has ever been reported in the United States. However, several lines of evidence suggest that some strains of *E. tarda* can cause diarrhea: 1) isolation rates are higher in symptomatic persons than in controls, 2) antibodies to *E. tarda* are present in serum, 3) edwardsiellae can be isolated from both the stool and blood of persons with gastroenteritis and septicemia, and 4) enteropathogenic mechanisms (see Pathogenicity) can be identified for select *E. tarda* isolates (Gilman et al., 1971; Janda and Abbott, 1993; Janda and Abbott, 1998). *Edwardsiella* gastroenteritis is usually a self-limiting infection. Several forms of *E. tarda*-associated gastroenteritis have been described including enteric fever, secretory enteritis and a dysenteric (bloody) form (Janda and Abbott, 1993). Secretory diarrhea is the most common form of illness with a low-grade fever and watery stools (5 bowel movements/day) as the predominant symptoms. Documented sources of exposure leading to *E. tarda* gastroenteritis include handling amphibians or possessing ornamental aquariums (Nagel et al., 1982; Marsh and Gorbach, 1982; Vandepitte et al., 1983).

Septicemia associated with *E. tarda* is rare. Although one report states that over 300 cases have been published (Peyrade et al., 1997), probably only 25 to 30 cases of *E. tarda* bacteremia are well described in the medical literature. Though *E. tarda* septicemia is an uncommon illness, the mortality rate associated with infection approaches 50% (Janda and Abbott, 1993). Patients typically present with fever and less often (36–50%) with diarrhea, chills, hypotension, epigastric pain, nausea and vomiting (Janda and Abbott, 1993; Janda and Abbott, 1998).

Approximately three-quarters of persons developing *E. tarda* sepsis are immunocompromised or have one or more other serious underlying conditions. Common maladies include pre-existing hepatobiliary disease, malignancy, diabetes mellitus and sickle cell disease (Jaruratanasirikul and Kalnauwakul, 1991; Janda and Abbott, 1993; Wu et al., 1995; Matsushima et al., 1996; Peyrade et al., 1997; Osiri et al., 1997). Recently, Schoenfeld et al. (1995) described a case of bacteremia in a 71-year-old man with chronic autoimmune thyroiditis whose blood and urine was positive for *E. tarda*; a source for this unusual infection was not identified. He was treated with gentamicin/mezlocillin, to which he responded favorably. Janda and Abbott (1993) noted that many persons presenting with *E. tarda* septicemia have underlying conditions associated with iron overload. These conditions include red cell sickling, neonatal jaundice, hepatic cirrhosis and leukemia. Matsushima et al. (1996) reported the first case of *E. tarda* septicemia associated with necrotizing fasciitis. This fatal infection in a 67-year-old Japanese man with liver cirrhosis and hepatoma, developed 15 days after his initial hospitalization. His right leg became edematous with hemorrhagic bullae; both blood and material from the bullae yielded *E. tarda*. Laboratory findings suggested that he died of disseminated intravascular coagulation. *Edwardsiella* bacteremia (complicated by uterine pyomyoma) was recently described in a 46-year-old aboriginal woman (Yang and Wang, 1999). This case of uterine pyomyoma, a rarely reported condition, was believed to have occurred via hematogenous seeding of bacteria on the large infarcted uterine myoma. Interestingly, the onset of her symptoms appeared a few hours after consuming three bottles of wine. Other conditions recently associated with *Edwardsiella* septicemia include septic arthritis and cellulitis (Osiri et al., 1997; Fournier et al., 1997). Although the initial sources of infection for most cases of *Edwardsiella* septicemia are unknown, one report implicated contaminated seafood as the most likely vehicle for their case (Wu et al., 1995). Recently, Nettles and Sexton (1997) described a case of prosthetic valve endocarditis caused by *E. tarda*. The patient, a 41-year-old man with AIDS, presented with diarrhea, fever and shortness of breath. Transesophageal echocardiogram revealed multiple oscillating masses on the mitral prosthetic valve and two sets of blood cultures grew *E. tarda*. His recent medical history was significant for injuring his hand on the barb of a catfish before consuming it, cooked medium rare.

This organism is also occasionally recovered from wounds, but its role in pathology is often unclear because these infections are often

polymicrobial. As with monomicrobial cases of septicemia caused by *edwardsiellae*, there are very few good, documented reports describing *E. tarda* as a bona fide wound pathogen. The medical history of persons infected with *E. tarda* often reveals exposure to freshwater environments or activities (swimming, diving and fishing). Penetrating injuries from catfish spines are the most common precipitating factor leading to wounds infected with *E. tarda* (Hargreaves and Lucey, 1990; Murphey et al., 1992; Banks, 1992; Ashford et al., 1998), and these usually occur on the extremities. Ashford et al. (1998) reported a case of *E. tarda* septic arthritis in a 20-year-old professional angler that developed after the pectoral-fin spine of a Lake Argyle or Ord River catfish (*Arius midgleyi*) punctured his knee. He underwent repeated arthrotomies, pulse lavage, drainage and treatment with multiple chemotherapeutic agents (flucloxacillin, gentamicin) before his infection resolved. Occasionally, coinfections of *E. tarda* with other aquatic microbial species such as *Aeromonas hydrophila* are reported (Vartian and Septimus, 1990; Hargreaves and Lucey, 1990; Murphey et al., 1992). These infections can vary dramatically from mild cellulitis to life-threatening soft tissue infections including gas gangrene (Hargreaves and Lucey, 1990; Janda and Abbott, 1998).

Abscesses, another type of wound infection involving the collection of pus in a cavity, rarely involve *E. tarda*. However, eight cases of *E. tarda* associated with hepatic abscesses have been reported (Kourany et al., 1977; Zighelboim et al., 1992; Janda and Abbott, 1998). Patients with these abscesses commonly present with fever accompanied by abdominal or right quadrant pain; most of these illnesses have occurred in healthy persons with no known risk factors (Janda and Abbott, 1998). The mortality rate associated with this disease is ~40%. Other rare wound infections associated with *E. tarda* include a tubo-ovarian abscess in a 42-year-old woman who had recently eaten poki (raw fish) just before developing symptoms suggestive of acute appendicitis (Pien and Jackson, 1995).

Other body fluids from which *E. tarda* has been isolated include bile and urine (Tan et al., 1977). The significance of many of these isolates cannot be determined because of a lack of clinical information.

Pathogenicity

The study of which factors or virulence determinants regulate the ability of both *E. ictaluri* and *E. tarda* to cause disease in fish, humans and other animals is in its infancy. Waltman et al. (1986) have described two enzymatic activities

with pathogenic potential in strains of *E. ictaluri*. All strains (n = 100) produced a chondroitinase and ~97% produced a hemolysin. The chondroitinase may conceivably be involved in the formation of chronic "hole-in-the-head" lesions (Fig. 5) by degradation of native cartilage (Shotts et al., 1986; Thune et al., 1993). The β -hemolysin, a cytolytic protein, may be responsible for some of the hemodynamic changes (hematocrit, hemoglobin, plasma protein and glucose) associated with *E. ictaluri*-infected fish (Thune et al., 1993). The ulcerative lesions associated with ESC (e.g., petechial hemorrhages) might also be partially due to damage and lysis of host cells by direct contact with β -hemolysin (Fig. 4). Besides these two activities, *E. ictaluri* strains are refractory to the bactericidal effects of fresh human serum (Janda et al., 1991a; Reger et al., 1993). Resistance to complement-mediated lysis might facilitate the rapid invasion and migration of *edwardsiellae* from the intestine into internal organs during a fulminant episode of ESC (Thune et al., 1993). Adherence to tissue in the initial stages of infection may be facilitated by mannose-sensitive or mannose-resistant hemagglutinins acting as non-fimbrial adhesins (Wong et al., 1989; Thune et al., 1993). Strains of *E. ictaluri* do not possess significant amounts of glycocalyx, which might aid in adherence, on their cell surfaces as determined by electron microscopic analysis of ruthenium-stained cells (Wong et al., 1989).

There are several candidate virulence factors present in *E. tarda* that might play key roles in the development of diarrhea. Because *E. tarda* can cause both a secretory and bloody form of gastroenteritis, it is not surprising that potential factors operative in each type of infection have been identified. Marques et al. (1984) found *E. tarda* strains could invade HeLa cells (an epithelial cell line derived from a human adenocarcinoma), although all 12 isolates were negative in the keratoconjunctivitis (Sereacuteny test) assay. Janda et al. (1991b) confirmed the invasive ability of *E. tarda* and *E. hoshinae* (Fig. 6) in HEp-2 cells (a line derived from a human hepatocellular carcinoma; Fig. 7); these authors also detected the expression of a strong cell-associated β -hemolysin in *E. tarda* isolates.

The ability of *E. tarda* strains to invade non-professional phagocytes might be related to its ability to cause bloody diarrhea. Fish isolates of *E. tarda* invade epithelioma papillosum of carp (EPC) cells in vitro, suggesting that some of the invasive disease seen in piscine species caused by this microbe may be related to this property (Ling et al., 2000). Invasion appears to be a microfilament- and protein tyrosine kinase-dependent process as both cytochalasin D and genistein inhibit this process (Janda et al.,

Fig. 6. The adherence of *E. tarda* to HEp2 cells (A) magnification $\times 4,500$; (B) single bacteria in membrane-bound vesicles 30 min postinfection, magnification $\times 15,000$; (C) 2.5 h postinfection, magnification $\times 4,500$ (D) 3.5 h postinfection, magnification $\times 3,000$. (From Strauss et al., 1997, with permission.)

Fig. 7. HEp2 cells invaded by *E. tarda*, magnification $\times 200$.

1991b; Ling et al., 2000). Subsequently, two β -hemolysins from *E. tarda* have been cloned and sequenced. The first, cloned from strain ET16, resides in an open-reading frame (ORF) of ~933

bp encoding for a 311 amino acid polypeptide with a molecular mass of 34 kDa (Chen et al., 1996). The structural gene for this β -hemolysin shares over 90% homology to the hemolysin BL of *Bacillus cereus* (Hirono et al., 1997). The frequency of this gene in *E. tarda* isolates is unknown. A second β -hemolysin from *E. tarda* strain MZ8901 has been cloned and sequenced by Hirono et al. (1997). The gene, designated *ethA*, resides in an ORF of 4,782 bp that encodes for a 165.3 kDa product. The deduced amino acid sequence of EthA shares the highest degree of homology (47%) with the ShlA hemolysin of *Serratia marcescens* (Hirono et al., 1997). All 72 *E. tarda* strains tested reacted with an *ethA* probe, indicating that this appears to be the predominant β -hemolysin carried by most isolates. A study by Strauss et al. (1997) found that a transposon-mutagenized strain of *E. tarda* is noncytotoxic and defective for hemolysin production (Fig. 8) and is also unable to enter Hep-2 cells. This hemolysin appears to be very similar or identical to that described by Hirono et al. (1997). This implies that both hemolytic and invasive capabilities of edwardsiellae are linked

Fig. 8. Wild type (WT) *E. tarda* and a nonhemolytic mutant (*hly*⁻) of *E. tarda* on blood agar. (From Strauss et al., 1997, with permission)

Fig. 9. Deferrated L agar seeded with *E. tarda* with sterilized suspensions of transferrin, hemin, ferritin, protoporphyrin IX, hemoglobin and hemeatin (clockwise, starting at 1 o'clock) added to individual wells. In this iron-starved medium, growth of *E. tarda* occurred only in the presence of hemin, hemoglobin and hemeatin.

together. The hemolysin is also regulated by the availability of iron (Janda and Abbott, 1993; Fig. 9).

Elevated levels of hemolysin are produced by *E. tarda* strains under iron-limited conditions and two putative ferric uptake regulator (*Fur*) binding sites are on the 5' upstream region of the activation/secretion protein gene *ethB* overlapping the promoter region and ribosome-binding site (Janda and Abbott, 1993; Hirono et al., 1997). Thus expression is upregulated under iron-limited conditions and downregulated in the presence of an excess of iron.

A heat-stable (60°C, 30 min; 100°C, 15 min) enterotoxin has been detected in 3 of 25 *E. tarda* strains employing the rabbit ligated ileal loop assay (Bockemühl et al., 1983). This enterotoxin did not cause Chinese hamster ovary (CHO) cell elongation. Conceivably, this enterotoxin could be operative in cases of secretory diarrhea associated with *E. tarda*. Also, *E. tarda* has recently been shown to induce plasma membrane ruffling in HEp-2 cells, a phenomenon that does not correlate with adhering bacteria (Phillips et al., 1998). The authors suggest that this may involve a distinct pathogenic mechanism in *E. tarda*.

A number of other potential virulence factors have been identified in *E. tarda* strains. These include hemagglutinins, dermatonecrotic substances, siderophores, and resistance to complement-mediated lysis (Ullah and Arai, 1983; Wong et al., 1989; Janda et al., 1991a). Their possible role in pathogenicity is speculative at present.

The Genus *Citrobacter*

DIANA BORENSHTEIN AND DAVID B. SCHAUER

Introduction

Members of the genus *Citrobacter* are Gram-negative, nonsporeforming rods belonging to the family Enterobacteriaceae and, as the name suggests, usually utilize citrate as a sole carbon source. These facultative anaerobes typically are motile by means of peritrichous flagella. They ferment glucose and other carbohydrates with the production of acid and gas. They are oxidase negative, catalase and methyl red positive, Voges-Proskauer negative, and do not decarboxylate lysine. Taxonomically, the genus *Citrobacter* is most closely related to *Salmonella* and *Escherichia*.

In 1928, Braak described two strains of bacteria capable of forming trimethylene glycol from glycerol under anaerobic conditions. In honor of Freund's 1881 observation of trimethylene glycol as a fermentation product of glycerol, the strains were designated "*Bacterium freundii*" (Braak, 1928). One of these strains (ATCC 8454) was among the citrate-utilizing, lactose-fermenting coliforms that Werkman and Gillen designated "*Citrobacter freundii*" in 1932 (Werkman and Gillen, 1932). This classification was not universally accepted and several synonyms were used to describe these organisms including *Escherichia freundii*, *Colobactrum freundii*, *Paracolobactrum freundii*, *Salmonella ballerup*, *Salmonella hormaechei*, the Ballerup group, the Bethesda group, and the Bethesda-Ballerup group. In 1958, the International Subcommittee on the Taxonomy of the Enterobacteriaceae approved the name *C. freundii* for this heterogeneous group of bacteria. Subsequently, two groups of bacteria that were similar to *C. freundii* were recognized. The first was designated "*C. koseri*," "*C. diversus*," or "*Levinea malonatica*" by different researchers, and the other was designated "*L. amalonaticus*" (The Genus *Citrobacter* in the second edition). Eventually, these bacteria were included in the genus *Citrobacter*, and Frederiksen (1990) requested that the junior synonym *C. diversus* be formally replaced with *C. koseri*. In 1993, the Judicial Commission of the International Committee on Systematic Bacteri-

ology granted the request (Joint Commission of the International Committee on Systematic Bacteriology, 1993), and recognized *C. koseri* as the appropriate name. That same year, Brenner et al. (1993) introduced significant changes to the classification of the genus. Characterization of 112 strains for DNA relatedness using DNA-DNA hybridization resulted in the recognition of 11 distinct *Citrobacter* species. These groups were called "genomospecies" because the classification was based on DNA relatedness, but the species could also be distinguished by their biochemical profiles. In addition to *C. freundii*, *C. koseri* and *C. amalonaticus*, five new species (*C. farmeri*, *C. youngae*, *C. braakii*, *C. werkmanii* and *C. sedlakii*) were identified. The three other species (genomospecies 9, 10 and 11) were later named *C. rodentium* (Schauer et al., 1995), *C. gillenii* and *C. murlinae* (Brenner et al., 1999), respectively. A summary of the *Citrobacter* species and their type strains is presented in Table 1. More details on the historical taxonomy of the genus, up until the year 1992, can be found in the first and second editions of this text (Farmer, 1981; The Genus *Citrobacter* in the second edition).

Table 1. Species of the genus *Citrobacter* and their type strains.

Species ^a		Type strain	
Number	Name	ATCC number	GenBank accession
1	<i>C. freundii</i>	ATCC 8090	AF025365
2	<i>C. koseri</i>	ATCC 27028	AF025372
3	<i>C. amalonaticus</i>	ATCC 25407	AF025370
4	<i>C. farmeri</i>	ATCC 51112	AF025371
5	<i>C. youngae</i>	ATCC 29935	None
6	<i>C. braakii</i>	ATCC 51113	AF025368
7	<i>C. werkmanii</i>	ATCC 51114	AF025373
8	<i>C. sedlakii</i>	ATCC 51115	AF025364
9	<i>C. rodentium</i>	ATCC 51116	AF025363
10	<i>C. gillenii</i>	ATCC 51117	AF025367
11	<i>C. murlinae</i>	ATCC 51118	AF025369

^aOriginal genomospecies numbers from Brenner et al. (1993); species names from Brenner et al. (1993), except *C. rodentium* (Schauer et al., 1995), and *C. gillenii* and *C. murlinae* (Brenner et al., 1999).

Citrobacter species are infrequently isolated from stool and occasionally cause infections in people and in animals. *Citrobacter freundii* and *C. koseri* are regarded as opportunistic pathogens, and most of the other species of *Citrobacter* have been isolated frequently enough from the urine, blood and wounds, that they are presumed to be pathogenic as well. Nonetheless, the clinical significance of individual species of *Citrobacter* as well as possible differences in pathogenesis remain largely undetermined. Representative biochemical reactions for the 11 *Citrobacter* species are presented in Table 2. A brief description of each species follows.

Citrobacter freundii is the type species of the genus. It produces H₂S abundantly in triple sugar iron (TSI) agar or similar media (such as Kligler agar), but does not typically ferment sodium malonate or produce indole (Sedlak, 1973). Brenner et al. have subdivided the species into 7 biotypes (Brenner et al., 1999).

Citrobacter koseri does not produce H₂S in TSI agar, but H₂S is detected using more sensitive media such as ferrous chloride-gelatin or lead acetate. Lysine is not decarboxylated (Sedlak, 1973), and there is no growth in KCN (Brenner et al., 1993). *Citrobacter koseri* can be differentiated from other species of *Citrobacter* on the basis of its ability to produce acid from adonitol and D-arabitol.

Citrobacter amalonaticus is typically positive for indole production, negative for H₂S production on TSI agar, and grows in KCN. It utilizes citrate but does not ferment malonate.

Citrobacter farmeri (Brenner et al., 1993) corresponds to species 4 and is named in honor of John J. Farmer III. It is positive for indole production and negative or delayed positive for citrate utilization. It produces arginine dehydrolase and ornithine decarboxylase; and produces acid from α -methyl-D-glucoside, melibiose, raffinose, and sucrose; and can utilize benzoate, 4-hydroxybenzoate, malitol, D-melibiose, 1-*O*-methyl- α -galactoside, palatinose, protocatechuate, D-raffinose, and sucrose, but not *m*-coumarate, dulcitol, or malonate as sole carbon sources.

Citrobacter youngae (Brenner et al., 1993) corresponds to species 5 and is named in honor of Viola M. Young. It is typically indole negative, positive or delayed positive for citrate and arginine dihydrolase, and negative for ornithine decarboxylase. It produces acid from dulcitol but not from melibiose and is able to utilize dulcitol, 3-phenylpropionate, and L-sorbose, but not gentisate, 3-hydroxybenzoate, malonate, D-melibiose, 1-*O*-methyl- α -galactoside, 3-*O*-methyl-D-glucose, or tricarballoylate as sole carbon sources.

Citrobacter braakii (Brenner et al., 1993) corresponds to species 6 and is named in honor of Hendrik R. Braak. It is characterized by variable indole production, positive or delayed positive citrate utilization, arginine dehydrolase, and ornithine decarboxylase activity. It does not produce acid from salicin or sucrose and can utilize *m*-coumarate, 1-*O*-methyl- α -galactoside, 3-phenylpropionate, and L-tyrosine (delayed), but not L-sorbose as sole carbon sources. Two biotypes have been described, which differ primarily in their ability to utilize 4-aminobutyrate, lactose and lactulose as sole carbon sources (Brenner et al., 1999).

Citrobacter werkmanii (Brenner et al., 1993) corresponds to species 7 and is named in honor of Chester H. Werkman. It is negative for indole production and ornithine decarboxylase, and positive for citrate and arginine dehydrolase. It does not produce acid from dulcitol, melibiose or sucrose, and utilizes *m*-coumarate, D-lyxose, malonate, 3-phenylpropionate, L-sorbose and D-tartrate, but not dulcitol, 4-hydroxybenzoate, D-melibiose or 1-*O*-methyl- α -galactoside as sole carbon sources.

Citrobacter sedlakii (Brenner et al., 1993) corresponds to species 8 and is named in honor of Jiri Sedlak. It is positive for indole production, arginine dehydrolase, ornithine decarboxylase, and positive or delayed positive for citrate. It produces acid from dulcitol and melibiose, but not from sucrose, and it utilizes benzoate, dulcitol, 4-hydroxybenzoate, *myo*-inositol, lactulose, malonate, 1-*O*-methyl- α -galactoside and protocatechuate, but not 5-ketogluconate or L-sorbose as sole carbon sources.

Citrobacter rodentium (Schauer et al., 1995) corresponds to *Citrobacter* species 9 and the species name refers to gnawing animals. It is negative for indole and H₂S production, citrate utilization (within 2 days), growth in KCN, and arginine dihydrolase and is ornithine decarboxylase positive. It is typically nonmotile, but some reports describe delayed motility after 4 days (Brenner et al., 1999). *Citrobacter rodentium* does not produce acid from melibiose, sucrose, dulcitol or glycerol but is positive for malonate utilization. The organism has only been isolated from rodents and is the causative agent of transmissible murine colonic hyperplasia (Luperchio and Schauer, 2001). It is the only known attaching and effacing bacterial pathogen of mice.

Citrobacter gillenii (Brenner et al., 1999) corresponds to species 10 and is named in honor of George Francis Gillen. It is negative for the production of indole and ornithine decarboxylase, positive for utilization of malonate, delayed positive for growth on citrate, and usually delayed positive for the production of arginine dihydrolase. In addition, it is negative for urease

Abbreviations: TSI, triple sugar iron; ONPG, and *o*-nitrophenyl- β -D-galactopyranoside.

^aTests read after 2 and 7 days of incubation at $36 \pm 1^\circ\text{C}$. Results are expressed as percent of strains positive within 2 days, with the percent of strains giving delayed positive reactions (3–7 days) in parentheses. A more complete list of biochemical test results can be found in the original publication. Citrate, Simmons; H₂S, TSI; arginine, arginine deaminase; ornithine, ornithine decarboxylase; nitrite, $\text{NO}_3 \rightarrow \text{O}_2$; and ONPG, *o*-nitrophenyl- β -D-galactopyranoside.

Modified from Brenner et al. (1999).

production and dulcitol fermentation and is unable to utilize gentisate, 3-hydroxybenzoate, 3-*O*-methyl-D-glucose, L-sorbose, or tricarballoylate as sole carbon sources.

Citrobacter murlinae (Brenner et al., 1999) corresponds to species 11 and is named in honor of Alma C. McWhorter-Murlin. It is positive or delayed positive for indole production and citrate utilization, usually is delayed positive for arginine dehydrolase, and is negative for ornithine decarboxylase. It produces acid from dulcitol and esculin (delayed), grows on sodium acetate (usually delayed) but does not utilize malonate. Dulcitol, D-lyxose, 1-*O*-methyl- α -galactoside (delayed), and L-tyrosine, but not malonate or protocatechuate, can be utilized as sole carbon sources.

Habitat

Most of what is known about the natural history of *Citrobacter* isolates is due to their occurrence as opportunistic pathogens in humans. They are believed to be commensal inhabitants of the intestine of humans and animals and, most likely as a consequence of fecal shedding, are present in the environment and can be recovered from water, sewage and soil (Sedlak, 1973; Brenner et al., 1999). Clinical isolates of *Citrobacter* species from humans have been characterized to some extent, but with the exception of *C. rodentium*, much less is known about *Citrobacter* isolates from animals and from the environment. In humans, *Citrobacter* are associated with urinary tract infections, wound infections, pneumonia, abscesses, septicemia, meningitis, and endocarditis in adults, as well as septicemia, meningitis, and brain abscesses in neonates (Graham and Band, 1981; Shamir et al., 1990; Tang et al., 1994; Shih et al., 1996; Arens et al., 1997; Dyer et al., 1997; Doran, 1999; Lu et al., 1999; Tellez et al., 2000; Lin et al., 2001; The Genus *Citrobacter* in the second edition).

Citrobacter accounts for approximately 1% of all cases of septicemia (Drelichman and Band, 1985). *Citrobacter* septicemia often occurs in elderly patients, is often hospital acquired, and almost always occurs in patients with underlying disease (Shih et al., 1996). The most common initial sites of infection are the urinary tract, the gastrointestinal tract, and wounds. Intra-abdominal tumors and hepatobiliary stones, in particular, have been implicated as common predisposing risk factors for *Citrobacter* septicemia (Drelichman and Band, 1985; Shih et al., 1996). Patients with *Citrobacter* bacteremia are more likely to have polymicrobial sepsis than patients with *E. coli* bacteremia. While *Citrobacter* septicemia is fatal in up to 50% of patients, the sever-

ity of the underlying medical condition clearly contributes to the unfavorable outcome.

Citrobacter koseri is an important cause of septicemia and meningitis in neonates and young infants (Graham and Band, 1981; Doran, 1999). A high percentage of these patients develop brain abscesses. While most cases are sporadic with no obvious source of infection, nosocomial outbreaks in neonatal care units have been reported. The outbreaks were apparently caused by person-to-person spread rather than acquisition from an environmental point source. Despite improvements in diagnostic imaging techniques and antibiotic therapy, one-third of these patients die, and few recover without sequelae (for a review see Doran, 1999). It has been suggested that intracellular survival and replication of *C. koseri* within macrophages contributes to the development of brain abscesses (Townsend et al., 2003), although the details of this process have yet to be determined.

The significance of *Citrobacter* species in animals has not been firmly established. Fecal carriage and extraintestinal infections occur in mammals, birds and reptiles, including snakes, lizards and tortoises. *Citrobacter rodentium* has been isolated from laboratory mice and gerbils and causes transmissible murine colonic hyperplasia (for a review see Luperchio and Schauer, 2001). A locus of enterocytes effacement (LEE) pathogenicity island encoding a dedicated type III secretion system and its effectors is present in *C. rodentium* but not in other *Citrobacter* species. This LEE pathogenicity island is highly homologous to cognate pathogenicity islands in enteropathogenic *E. coli* and enterohemorrhagic *E. coli*, and *C. rodentium* infection in laboratory mice serves as an important model system for studying the pathogenesis of these gastrointestinal pathogens of humans. As reported by Luperchio et al. (2000), *C. rodentium* is the only naturally occurring attaching and effacing pathogen of rodents, and all of the isolates characterized to date appear to be clonal.

Isolation

Although there have been few efforts to selectively isolate *Citrobacter* species, they grow well on media commonly used for isolation of other Enterobacteriaceae, and selective media originally developed for the isolation of *Salmonella* have been used to isolate *Citrobacter* species from clinical specimens. These include enrichment media, such as tetrathionate (Miller), selenite F (Leifson), tetrathionate brilliant green (Kauffmann), and GN (Hajna). Plating media used for isolating *Salmonella*, including MacConkey lactose, Endo, desoxycholate cit-

rate (Leifson), bismuth sulfite (Wilson and Blair), and brilliant green (Kauffmann), can also be used to isolate *Citrobacter* species. Optimal temperature for growth is 30–37°C, and after 24 hours of growth, colonies are 2–3 mm in diameter. On MacConkey lactose agar, colonies can be red, pink or colorless, depending on how rapidly the individual *Citrobacter* isolate ferments lactose. Delayed utilization of lactose produces a characteristic “fisheye” colony morphology, featuring a pink or red center surrounded by a clear margin after 24 hours of growth.

Identification

The current taxonomic classification of *Citrobacter* species is based on DNA relatedness. Routine identification of *Citrobacter* isolates is accomplished by performing selected biochemical and carbon source utilization tests. The biochemical profiles of the 11 *Citrobacter* species are summarized in Table 2. More details on biochemical test results as well as carbon utilization results for determining biotypes have been published by Brenner et al. (Brenner et al., 1993; Brenner et al., 1999) and Schauer et al. (1995). On the basis of these reactions, a simple dichot-

omous key was developed by O'Hara et al. (1995) for presumptive identification (Fig. 1). These authors also evaluated commercial identification systems for their ability to accurately identify *Citrobacter* species. Most of the problems with misidentification will be resolved when the databases are updated to reflect the revised classification system of 11, rather than 3, valid species of *Citrobacter* (O'Hara et al., 1995).

DNA-based Systems

DNA RELATEDNESS (Hydroxyapatite Method of DNA-DNA Hybridization). Standards for genomospecies, or species defined by DNA relatedness, have been proposed as at least 70% related DNA under conditions optimal for DNA reassociation and 5% or less divergence (unpaired bases) within related sequences (Wayne et al., 1987). Brenner et al. (1999) used the additional criterion for defining *Citrobacter* species that DNA relatedness remain above 60% in reactions carried out under stringent conditions (75°C; whereas optimal conditions were 60°C). A summary of their DNA hybridization results is presented in Table 3.

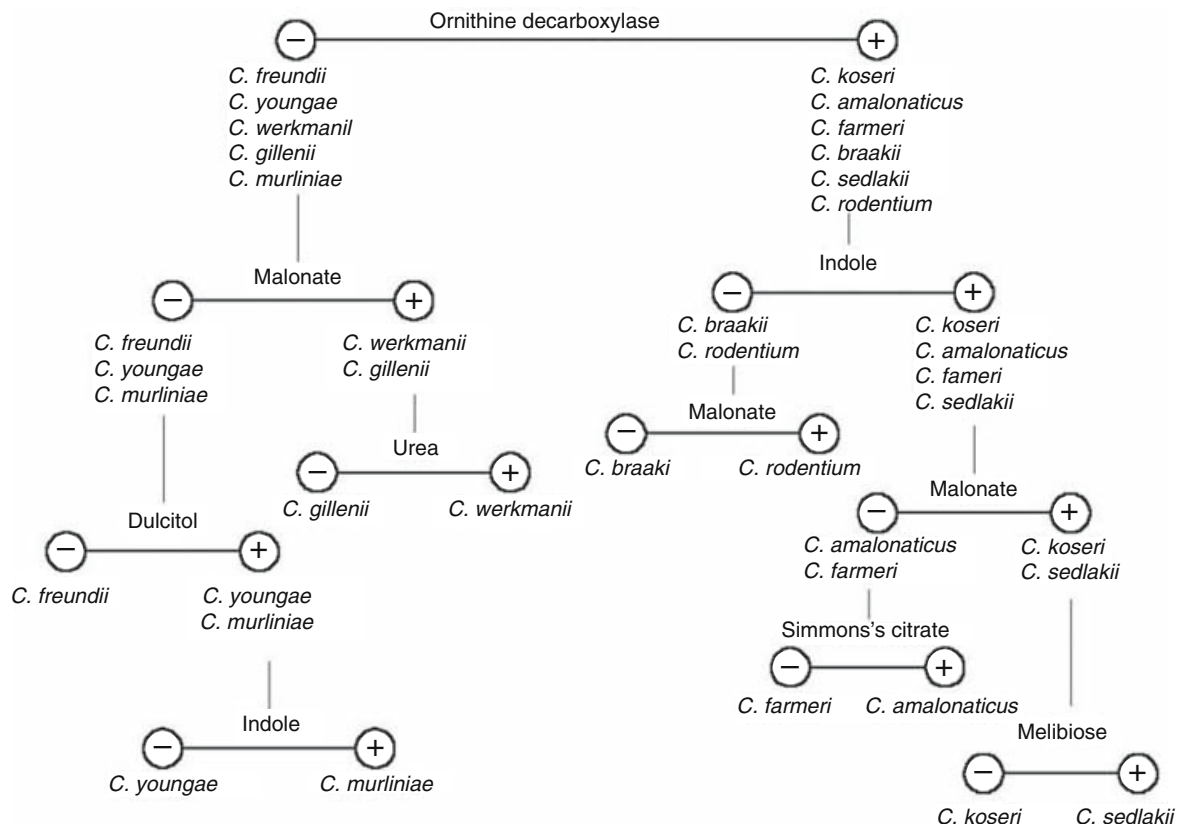

Fig. 1. Identification key for *Citrobacter* species, modified from O'Hara et al. (1995).

Table 3. DNA relatedness of *Citrobacter* species.^a

Species	Number of strains tested	% Relatedness at 60°C	Divergence	% Relatedness at 75°C
<i>C. freundii</i>	46	85	1.5	79
<i>C. koseri</i>	2	79	0.5	75
<i>C. amalonaticus</i>	5	76	1.0	76
<i>C. farmeri</i>	1	71	1.5	70
<i>C. youngae</i>	29	81	2.5	77
<i>C. braakii</i>	16	82	0.5	79
<i>C. werkmanii</i>	10	78	2.0	77
<i>C. sedlakii</i>	6	83	1.0	78
<i>C. rodentium</i>	3	94	0.5	ND
<i>C. gillenii</i>	11	86	1.0	92
<i>C. murliniae</i>	7	91	0.5	91

Abbreviation: ND, not done.

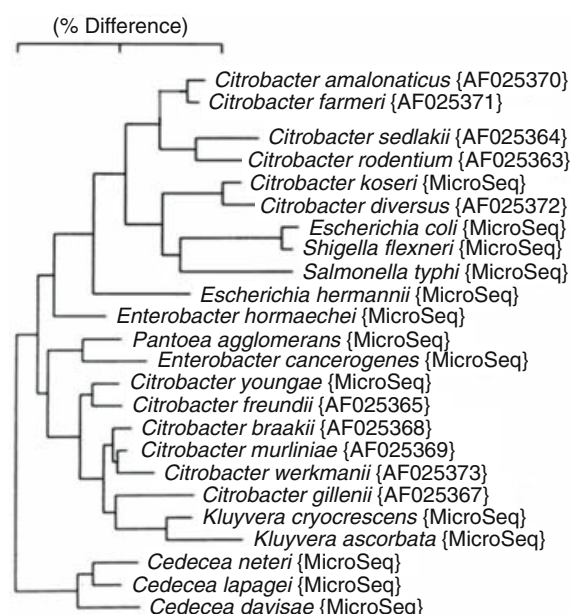

Fig. 2. Phylogenetic tree based on 16S rRNA sequence comparison, modified from Warren et al. (2000). The marker bar represents a 2% difference. GenBank accession numbers are listed. Microseq, sequences from the PE Applied Biosystems MicroSeq sequence database.

SEQUENCE ANALYSIS OF THE SMALL rRNA SUBUNIT (PHYLOGENETIC ANALYSIS). Genomespecies can also be defined on the basis of nucleotide sequence analysis of conserved portions of small rRNA subunits (Pace, 1997). Warren et al. (2000) have constructed a phylogenetic tree of the genus *Citrobacter* and related Enterobacteriaceae. The genus can be divided into three distinct groups, including 1) *C. freundii*, *C. youngae*, *C. braakii*, *C. werkmanii*, *C. gillenii* and *C. murliniae*; 2) *C. amalonaticus*, *C. farmeri*, *C. sedlakii* and *C. rodentium*; and 3) *C. koseri*, which is most closely related to *Escherichia coli*, *Shigella flexneri* and *Salmonella typhi* (Fig. 2).

REPETITIVE EXTRAGENIC PALINDROMIC PCR (REP-PCR). Phylogenetic relationships can also be deduced by means of high-resolution genotyping, such as repetitive extragenic palindromic polymerase chain reaction (rep-PCR) genomic fingerprinting. This method uses primers corresponding to naturally occurring interspersed repetitive elements in bacterial genomes (such as the REP, ERIC and BOX elements) for amplification of a series of products from genomic DNA (Versalovic et al., 1994). Rep-PCR profiles for the type strains of each *Citrobacter* species have been reported by Luperchio et al. (2000) and are presented in Fig. 3. Rep-PCR provides species-level identification for *C. rodentium*, with no apparent differences in amplification profiles between any of the isolates tested to date (Luperchio et al., 2000). However, for *C. koseri*, rep-PCR provides strain-level identification, with highly similar amplification profiles for epidemiologically linked isolates and distinct patterns for previously characterized strains within this species (Woods et al., 1992). The utility of rep-PCR for the other *Citrobacter* species has yet to be determined.

Serology

A serotyping scheme for *Citrobacter* isolates was established by West and Edwards in 1954 featuring 32 O serogroups, 87 H serogroups, and 167 different O:H serotypes (West and Edwards, 1954). This system was extended by Sedlak and Slajsova (1966) to include 42–48 O serogroups and more than 90 H serogroups (for review, see Sedlak, 1973). Miki et al. (1996) identified the 90 reference strains of the serotyping scheme according to current species definitions. Among this group of strains (which included isolates of *C. youngae*, *C. braakii*, *C. werkmanii*, *C. gillenii*, but only a limited number of *C. freundii sensu stricto*), most serotypes were found to be species

Fig. 3. Rep-PCR patterns amplified from DNA from *Citrobacter* species type strains, taken from Luperchio et al. (2000). Lane numbers represent the *Citrobacter* species numbers given in Table 1. M, 1-kb ladder standards.

specific. The serotyping system is not widely used for identification today, but it is important to recognize that serological cross-reactions between *Citrobacter* species and other Enterobacteriaceae (including *Salmonella* and *Escherichia*) do occur. Indeed, of the 20 chemotypes identified by Keleti and Luderitz (1971) based on the sugar composition of the lipopolysaccharide (LPS) of *Citrobacter* strains, 11 are identical to known *Salmonella* and *Escherichia* chemotypes. Cross-reactivity between *E. coli* O157 and *C. freundii* and *C. sedlakii* strains has been reported (Park et al., 1998; Nishiuchi et al., 2000; Vinogradov et al., 2000). Chemical structural data for the O-linked sugars of the LPS from a growing number of *Citrobacter* strains have been reported, including *C. freundii*, *C. youngae*, *C. braakii*, *C. sedlakii*, *C. rodentium* and *C. gillenii* (for a review, see Knirel et al., 2002).

Antibiotic Susceptibility

Antibiotic resistance in *Citrobacter* species, as in other bacteria causing nosocomial infections, is an emerging problem. *Citrobacter* species without acquired antibiotic resistance are susceptible to sulfonamides, trimethoprim, aminoglycosides, chloramphenicol, tetracycline, nalidixic acid, flu-

oroquinolones, nitrofurantoin, polymyxins and fosfomycin (The Genus *Citrobacter* in the second edition; Pepperell et al. 2002). Like other Enterobacteriaceae, *Citrobacter* species are resistant to erythromycin and other macrolides, lincosamides, fusidic acid, and vancomycin (The Genus *Citrobacter* in the second edition). Acquired resistance to quinolones has been reported and is primarily attributable to mutations in *gyrA* encoding the A subunit of DNA gyrase, although enhanced efflux pump activity may also contribute (Navia et al., 1999; Tavio et al., 2000). Acquired resistance to aminoglycosides has also been reported and can be attributed to aminoglycoside acetyltransferase genes carried on plasmids or located in the chromosome, often in association with integrons (Hannecart-Pokorni et al., 1997; Wu et al., 1997).

Perhaps the most important aspect of antibiotic susceptibility in *Citrobacter* species concerns β -lactams. Even without acquired resistance, *Citrobacter* isolates are typically resistant to β -lactams such as ampicillin and carbenicillin. *Citrobacter* species that cluster with *C. freundii*, including *C. youngae*, *C. braakii*, *C. werkmanii* and *C. murlinae* (Fig. 2), possess an inducible class C β -lactamase on the chromosome that also confers resistance to early generation cephalosporins (Naas et al., 2002). *Citrobacter* species that cluster with *C. koseri*, including *C. sedlakii* and *C. rodentium* (Fig. 2), possess an inducible class A β -lactamase on the chromosome (Petrella et al., 2001). Antibiotic therapy with extended-spectrum cephalosporins is known to select for resistant *Citrobacter* isolates in vivo (The Genus *Citrobacter* in the second edition). In *Citrobacter* species with class C β -lactamase activity, resistance to extended-spectrum cephalosporins is associated with overproduction of β -lactamase due to mutations in the gene encoding AmpD (an amidase that interacts with AmpR, which is a transcriptional regulator of the LysR family). Resistance to extended-spectrum cephalosporins in *Citrobacter* species with class A β -lactamase activity is less well characterized.

The Genus *Shigella*

YVES GERMANI AND PHILIPPE J. SANSONETTI

Introduction

Shigella is a Gram-negative, nonmotile, non-sporeforming, non-lactose-fermenting, facultatively anaerobic bacillus belonging to the family Enterobacteriaceae. It causes bacillary dysentery or shigellosis, as do enteroinvasive *Escherichia coli* strains (EIEC). The disease naturally occurs only in humans and primates. It is characterized, in its classical form, by acute colonic and rectal mucosal inflammation that leads to the triad of the dysenteric syndrome: fever, intestinal cramps, and passage of blood and mucus in diarrheal stools. *Shigella dysenteriae* 1 was the first of the four *Shigella* species to be described in 1898 by the Japanese microbiologist K. Shiga, thus the name of Shiga bacillus. The four species share several major characteristics such as lack of motility, optimal growth at 37°C, oxidase-negative character, and lack of growth in synthetic media containing salts and a simple carbon source, unless glucose and nicotinic acid are added. Some isolates may require the addition of certain amino acids, purines or vitamins. The chromosomal DNA of *Shigella* has a G+C content of about 50 mol%. The *Shigella* genus is very closely related to the species *Escherichia coli*; because the degree of homology of their chromosomal DNAs is close to 100%, considering *Shigella* as a member of the genus *Escherichia* is regarded as justifiable (Brenner et al., 1973). However, whereas *Escherichia coli* isolates are usually prototrophic, motile, and able to ferment many sugars, *Shigella* isolates are auxotrophic, nonmotile, ferment few sugars and, with a few exceptions, produce no gas in the presence of glucose. *Shigella* spp. therefore appear to be unique among the Enterobacteriaceae, in that their species status is maintained for reasons that are historical and linked to their particular metabolic profile and capacity to cause dysentery.

Bacteriological Characters

The genus *Shigella* consists of four species, *S. dysenteriae* (subgroup A), *S. flexneri* (subgroup

B), *S. boydii* (subgroup C) and *S. sonnei* (subgroup D), characterized by biochemical and serological properties. The subgroup A differs from the other subgroups by its inability to ferment mannitol. *Shigella* serotypes are differentiated on the basis of their somatic O antigens.

Shigella spp. express numerous “negative” characters. Isolates are always nonmotile and nonflagellated. They do not grow on synthetic media with Simmons’ citrate, they do not express a deaminase for phenylalanine or tryptophan, and they are also negative for the following characters: urease, lysine and arginine decarboxylase, production of H₂S (on triple-sugar-iron agar), growth in KCN medium, utilization of Christensen’s citrate or malonate, oxidation of gluconate, or liquefaction of gelatin. They give a positive methyl red and a negative Voges-Proskauer reaction. Like all *Enterobacteria*, *Shigella* spp. ferment glucose, but they (with the exception of *S. flexneri* 6, *S. boydii* 13 and 14 and *S. dysenteriae* 3) do not produce gas. Media containing lactose are not acidified by isolates belonging to *S. dysenteriae*, *S. flexneri* and *S. boydii* species. However, slow acidification (several days) may occur with *S. sonnei*. Adonitol, inositol and salicin are not fermented, but saccharose is slowly fermented by *S. sonnei*.

Mannitol is a key sugar in *Shigella* classification because, with rare exception, it is not fermented by *S. dysenteriae* and is fermented by all isolates belonging to the three other species.

The serotypic and biochemical characteristics that define the four species are summarized in Table 1 (Lindberg et al., 1991).

Shigella dysenteriae (Subgroup A)

This subgroup comprises 12 serotypes, each possessing a distinct antigen. Crossreactions are very limited within this subgroup. Serotype 1 corresponds to the *Shiga bacillus*, which is also characterized by its production of the Shiga toxin (see below). Serotypes 2, 7 and 8 produce indole. *S. dysenteriae* 1 also produces a very active β -galactosidase (*o*-nitrophenyl- β -D-galactyl pyranoside [ONPG] test positive in less than 1 h) and

Table 1. Characteristics of *Shigella*.

	Mannitol	Indole	Serotypes	Antigens	Comments
<i>S. dysenteriae</i> (subgroup A)	–	–	1, 3, 4, 5, 6, 10, 11, 12, 13 2, 7, 8	Each serotype possesses a distinct antigen	ONPG+, catalase–, arabinose–
<i>S. flexneri</i> (subgroup B)	+	[–] [+] –	1, 2 3, 4, 5 6	Several antigenic determinants are shared by the species members. Coagglutination is possible and highly absorbed antisera are needed.	<i>S. flexneri</i> 6 var. Manchester and var. Newcastle are gas + ^a
<i>S. boydii</i> (subgroup C)	+	– +	1, 2, 3, 4, 6, 8, 10, 12, 14, 18 5, 7, 9, 11, 13, 15, 16, 17	The 13 serotypes are antigenically distinct, excepted serotypes 10 and 11 sharing a common antigen other than their specific antigen.	<i>S. boydii</i> 10 is ADH+, arabinose+, threolose+ <i>S. boydii</i> 14 is gas+, mannitol–, maltose+, sorbitol–, arabinose+, threolose+, ADH+ <i>S. boydii</i> 17 is ADH–, arabinose+, threolose+ <i>S. boydii</i> 9 is ONPG+ (African strains may be lactose+)
<i>S. sonnei</i> (subgroup D)	+	–	Centairs only one serotype.	It undergoes antigenic variation in phase I (smooth and virulent) and II (rough non-virulent). A plasmid encodes the form I antigen and the ability to invade intestinal epithelial cells. The phase I is not antigenically related to other <i>Shigella</i> groups but identical with <i>Plesiomonas</i> <i>shigelloides</i> serotype C27.	<i>S. sonnei</i> usually ferments lactose or saccharose after 3, 4 days at 37°C 4 major biotypes (99% of the strains): a: ONPG+, xylose–, rhamnose+ g: ONPG+, xylose–, rhamnose+ d: ONPG–, xylose+, rhamnose+ f: ONPG–, xylose–, rhamnose+

does not produce catalase, an extremely unusual feature among Enterobacteriaceae. Certain isolates of *S. dysenteriae* 6 also may possess a β -galactosidase, but the ONPG test turns positive very slowly (1 day).

Shigella flexneri (Subgroup B)

This subgroup comprises 6 serotypes whose antigenic schemes are summarized in Table 2. These six main serotypes are each characterized by a different specific type antigen. Serotypes can further be divided according to the group antigens. Subtyping requires highly absorbed antisera and can thus be performed only at reference centers where these antisera are available. Type antigens are designated by roman digits and group antigens by Arabic digits. With the exception of *S. flexneri* serotype 6 (whose assignment to subgroup B is still challenged by some authors), group 3,4 antigen is present as the primary structure (Simmons et al., 1987). Figure 1 shows the composition of the repetitive polysaccharide subunits (i.e., the somatic antigen) that polymerize as O-side chains of the lipopolysac-

charide (LPS), supporting serotype specificity (Ewing, 1986). Some isolates have lost expression of their type-specific antigen, thus showing only their group antigen; they are identified as X and Y. Isolates of *S. flexneri* 1–5 may be indole positive.

Fig. 1. Sugar composition of repetitive subunits that compose the *S. flexneri* somatic antigens. Further glycosylation and/or acetylation defines serotype specificity.

S. boydii (Subgroup C)

This subgroup has 18 serotypes, all of which are antigenically distinct, with two exceptions (serotypes 11 and 12), which share a common antigen that does not correspond to their specific antigen. Strains belonging to serotypes 5, 7, 9, 11, 13 and 15 are indole positive. Strains of serotype 14 are ADH positive and some isolates of serotypes 13 and 14 can produce gas in the presence of glucose.

S. sonnei (Subgroup D)

Unlike other *Shigella* species, *S. sonnei* has a single serotype that undergoes a phase variation from a smooth, virulent, phase I to a rough, avirulent, phase II, which has lost the capacity to synthesize its O-side chains. The phase I antigen is not antigenically related to any other *Shigella* serotype, but is similar to serotype C27 of *Plesiomonas shigelloides*. The change from phase I to II is irreversible and has been shown to be due to the loss of a large virulence plasmid (Sansone et al., 1980; Sansone et al., 1982; Kopecko et al., 1980). Although corresponding to a single serotype, the species *S. sonnei* can be subdivided in biovars on the basis of the following characters: ONPG, xylose and rhamnose. The most frequent biovars are ONPG⁺, xylose⁻, rhamnose⁺ and ONPG⁻, xylose⁻, rhamnose⁺, whereas the least frequent is ONPG⁻, xylose⁺, rhamnose⁺.

Clinical Findings

The classical syndrome associated with *Shigella* is dysentery, which develops with an incubation

period of 1–4 days. However, the severity of dysentery varies widely from severe to asymptomatic infection (asymptomatic infections are common in highly endemic areas where up to 50% of all *Shigella* infections may be asymptomatic). In experimentally infected volunteers, the classical triad of shigellosis (fever, abdominal pain, and passage of blood and mucus in diarrheal stools) was observed only in half of those infected (DuPont et al., 1969). The disease usually begins with fever, anorexia, fatigue and malaise. Patients presenting with high fever, frequent bloody stools of small volume (sometimes grossly purulent), abdominal cramps or tenesmus, and showing large clumps of leukocytes in their feces, can be given presumptive diagnosis of bacillary dysentery. The typical illness usually begins with fever (38–40°C), with lower abdominal pain, watery diarrhea and malaise. Watery diarrhea may be brief or even absent. Severe dehydration is not a typical picture. However, in malnourished patients, the loss of water and electrolytes may cause dehydration and salt imbalance. Twelve to 36 hours later, diarrhea progresses to dysentery, blood, mucus and pus appearing in feces that decreases in volume (no more than 30 ml of fluid per kg per day). Stool frequency is variably increased, with 10–100 movements per day. During this second stage, shigellae multiply throughout the colonic mucosa, stimulating inflammatory infiltration with formation of abscesses. The pathogenesis of shigellosis involves invasion and inflammation of the colonic epithelium, destruction of the superficial mucosa, and production of ulcers. Recovery of bacteria in the blood is rare.

The disease always is localized to the rectosigmoid area, whereas more proximal portions of

Fig. 2. Mucosal inflammation and abscess formation in colonic mucosa in the course of shigellosis. L = intestinal lumen, C = crypt, MM = muscularis mucosae, SM = submucosa, M = mucosal layer. Arrowhead points to an abscess ulcerated into the colonic lumen. Arrow points to a crypt abscess (i.e., cryptitis). Picture is a gift from S. B. Formal.

the large intestine are less frequently affected. While dilated colonic crypts are common during early stages of dysentery, elongated crypts are seen only when the duration of disease exceeds seven days on average. In about 30% of patients, abscesses develop because crypts become heavily infiltrated with polymorphonuclear leucocytes. Histological damage is mostly in the distal large bowel (Fig. 2). A proctoscopy examination during this phase shows a swollen mucosa with mucus, hemorrhages, and ulcers resulting from the death of colonic mucosal cells, detachment of the epithelial layer, and rupture of the abscesses. The lesions are continuous and diffuse and may involve edema, erythema, focal hemorrhages, and occasionally a white mucopurulent layer that adheres to the intestinal wall. Bacteria usually are confined to the epithelium of the surface and upper third of the colonic crypts. An exudate consisting of colonocytes, polymorphonuclear granulocytes with whole or partly digested bacteria, and erythrocytes in a fibrin mesh may be found in the intestinal lumen. Damaged epithelial cells are shed and goblet cells are reduced in number. The epithelial monolayer frequently is infiltrated by polymorphonuclear cells, lymphocytes, and mast cells. In the crypt epithelium, activated intraepithelial lymphocytes are prevalent, and monocytes arrive at a later stage of the dysentery. Ulcerations may extend into the lamina propria and associate with an inflammatory infiltrate in the submucosa. Widespread vascular lesions also are seen, ranging from swollen or pyknotic vascular endothe-

lial cells to complete destruction of the endothelium.

Progression to clinical dysentery occurs in most patients with *S. dysenteriae* type 1 and is also common in *S. boydii* and *S. flexneri* infection. Conversely, infections due to *S. sonnei* are, in general, less severe than those caused by other subgroups; they are often associated with vomiting and watery diarrhea, and possibly with dehydration.

In the poorest areas, persistent diarrhea and chronic malnutrition are the most common chronic complications (Black et al., 1982). This chronic malnutrition syndrome may last for weeks to months, thus affecting growth, owing to protein-losing enteropathy. If the negative nitrogen balance is not corrected during convalescence, protein loss may cause severe growth retardation.

Although *S. dysenteriae* type 1 is the *Shigella* species that is most often associated with severe bacillary dysentery and complications, all *Shigella* species may give rise to fatal disease. Septicemia is rare, but episodes of *Shigella* bacteremia have been reported during bacillary dysentery, especially among malnourished children (Struelens et al., 1985) or adult patients with impaired immunity. In immunocompetent patients, when bacteremia occurs, a non-*Shigella*, Gram-negative species is isolated in about half of the cases (Bennish et al., 1991). Other reported complications include hypoglycemia (which may be lethal in infants; Bennish et al., 1990a), seizures (Bennish, 1991a), as well as rectal prolapse, toxic megacolon, hemolytic-uremic syndrome (HUS), and leukemoid reaction (Butler et al., 1984). Toxic megacolon may lead to intestinal perforation and HUS may cause death by renal failure and/or anemia. Shiga toxin is implicated in HUS, but the mechanisms behind the pathogenesis of these complications remain incompletely understood (Karpman et al., 1997). Post-*Shigella* reactive arthritis or full-blown Reiter's syndrome (sterile arthritis, uveitis and urethritis) are classical complications, particularly in persons expressing the HLA-B27 histocompatibility antigen.

Epidemiology

General Considerations

Shigella generally is considered to have a narrow distribution in nature, inhabiting essentially the intestinal tract of humans, as well as captive primates in which shigellosis naturally occurs. There is no evidence, however, that the disease naturally occurs, particularly in the wild in those monkeys, without prior contact with humans

(Carpenter et al., 1965; Takasaka et al., 1964). Although shigellae are difficult, if not impossible, to grow from environmental samples, they are consistently present, particularly in sewage, and accidental contamination of water supplies by sewage effluents is regularly followed by an outbreak of shigellosis. Most cases of shigellosis are individual cases following person-to-person transmission. Outbreaks are usually a response to food and/or water contamination.

The disease is endemic throughout the world, although 99% of the cases occur in the developing world. Shigellosis is a disease that affects the poorest populations of the planet. According to a review by Kotloff et al. (1999), the total number of *Shigella* episodes that occur each year throughout the world is estimated to be 164.7 million, including 163.2 million cases in developing countries, 1.1 million of which result in death. Children under 5 years account for 69% of all episodes of shigellosis and 61% of all deaths attributable to shigellosis. Although distributed throughout the world, the prevalence of bacillary dysentery differs from place to place. It is estimated that the incidence of shigellosis (cases per 100,000 per year) is 6.5 in the United States, 130 in Israel, 3.3 in the United Kingdom, 5.6 in Australia, and 1.8 in France (Kotloff et al., 1999). Epidemics of shigellosis always have occurred among humans who gather in poor hygienic conditions: armies during military campaigns, pilgrimages, and refugee camps. In spite of the numerous epidemiological studies available, there is still a great need for accurate and frequently updated evaluation of the disease burden.

TRANSMISSION Transmission of *Shigella* occurs through the fecal-oral route. It is typically spread by direct contact with an infected person because the bacteria can survive on skin. Studies have demonstrated that an important vehicle for transmission of shigellosis is the hand, and that *S. dysenteriae* type 1 survives for up to one hour in culturable form on a human's skin (Islam et al., 1997). A characteristic of shigellosis is the ease with which person-to-person transmission of the pathogens occurs (Mosely et al., 1962). This is presumably due to the very small infectious inoculum required. Studies on American volunteers experimentally infected with *Shigella* have shown that as few as one hundred shigellae given orally cause the disease in 25–50% of the cases (DuPont et al., 1989). Resistance of *Shigella* to gastric juice certainly accounts, although not exclusively, for this high infectivity. *Shigella* also can be transmitted by contaminated foods (lettuce, onions, coconut milk desserts, hamburgers, raw oysters, meat, soup and pasta dishes), thus resulting in outbreaks (Wennerås et al.,

2000; Rennels et al., 1986; Boyce et al., 1982). Flies may transmit shigellae from human feces to foods (Hardy et al., 1948; Levine et al., 1991). In water, shigellae can survive for at least six months at room temperature. When outbreaks occur in a day care setting, attack rates may be as high as 33–73% (Weissman et al., 1974; Kotloff et al., 1999; Pickering et al., 1990), and secondary cases may be detected in 26–33% of the families of those children, thus confirming the high infectivity of these pathogens, as well as the significant role of day care centers in the dissemination of bacillary dysentery to the community (Kotloff et al., 1999; Pickering et al., 1981; Weissman et al., 1975). Oral/anal and oral/genital sexual practices also represent means of transmission (Dritz et al., 1974; Drusin et al., 1976) and may explain, in part, why shigellosis became so prevalent among the homosexual community in San Francisco in the early eighties (Tauxe et al., 1988; Laughon et al., 1988; Quinn et al., 1983).

Shigellosis in Developing Countries

Shigellosis is associated mainly with conditions that characterize underdeveloped countries, such as malnutrition, poor personal hygiene, poverty, overcrowding, absence of food control, and inadequate water supplies. *Shigella* is a serious problem in developing countries because malnourished individuals suffer higher complication rates and prolonged disease. The disease may be fatal, especially among young children, as observed in Bangladesh (Bennish et al., 1991) where a *S. dysenteriae* type 1 epidemic was associated with a 42% increase in mortality in children aged 1–4 years. Since the late sixties, epidemics of bacillary dysentery involving *S. dysenteriae* type 1 have appeared in Central America (Gangarosa et al., 1969; Mata et al., 1969), sub-Saharan Africa (largely in refugee camps; Osisanya et al., 1988; Casalino et al., 1988), Central Africa (Ries et al., 1994; Germani et al., 1998a; Malengreau et al., 1983), South and Southeast Asia (Punyaratabandhu et al., 1991; Huilan et al., 1991; Adkins et al., 1987), and the Indian subcontinent including India (Rahaman et al., 1975), Bangladesh and Pakistan (Huilan et al., 1991). It also affects populations in areas of natural disaster (Kotloff et al., 1999; Keusch et al., 1989; Mosely et al., 1962). When multiresistant strains occur in these populations, or when a serotype is introduced that did not circulate before in the population, high attack rates are observed, and shigellosis often becomes a leading cause of death (Ries et al., 1994; Sack et al., 1997). In countries where shigellosis is endemic, it often exhibits seasonal peaks that can vary from one country to another. In Egypt and

in Bangladesh (Keusch et al., 1989), the transmission peak is in the hot dry season (mainly by use of contaminated water for consumption and decreased individual hygiene due to water scarcity); whereas in Guatemala (Mata et al., 1969), the peak is in the rainy season (owing to water-washed transmission during heavy rains).

The burden of shigellosis recently has been revisited (Kotloff et al., 1999), thus allowing emphasizing three major epidemiological characteristics of the disease. Shigellosis is essentially a disease of the developing world with 163.2 million cases/year leading to 1.1 million deaths, whereas only 1.5 million cases are observed in industrialized countries where lethal forms are rarely observed.

Shigellosis is primarily a pediatric disease, 69% of the total cases and 61% of the deaths occurring in children between 1 and 5 years old. In addition, severe diseases occur in non-breast-fed infants (Clemens et al., 1986) and shigellosis is uncommon in infants under 6 months (Wennerås et al., 2000; Kotloff et al., 1999; Bern et al., 1992). The rate of carriage may reach 1% among healthy children and 6% among children with other illnesses (Wennerås et al., 2000; Bennish et al., 1991; Hossain et al., 1994). Long-term carriage of *Shigella* (around one year) has been described in children (Wennerås et al., 2000). *Shigella* infections frequently are seen among children with chronic diarrhea, a condition that is frequently associated with malnutrition and stunted growth. Malnutrition is an important conditioning factor for lethal infection and not only predisposes for severe shigellosis, but the dysentery itself may give rise to negative caloric balance and growth retardation by several processes: protein loss during intestinal inflammation, food malabsorption, and lack of appetite. Often after resolution, catch-up growth does not occur (Bennish et al., 1991; Wennerås et al., 2000).

Unexpected mass displacement and gathering of people often face insufficient supplies of drinkable water, poor sanitation and malnutrition. In this setting, morbidity and mortality in all age groups can be important when outbreaks occur (Centers for Disease Control and Prevention, 1994). In 1994, during the epidemic of shigellosis in the former Zaïre, 20,000 patients died during the first month from bacillary dysentery among 800,000 Rwandan refugees. The causative strain was a multiresistant *S. dysenteriae* 1 isolate (Goma Epidemiology Group, 1995). High rates of morbidity and mortality also have been reported among refugees (Kotloff et al., 1999) from Somalia (Moore et al., 1993) and Kurdistan (Yip et al., 1993). *Shigella* is also a common etiologic agent of diarrhea among travelers to less developed regions, especially in the inter-tropical area. In their study, Kotloff et al. (1999) esti-

mated that the number of traveler's shigellosis cases originating from industrialized countries were 580,000 per year. Bacillary dysentery continues to affect soldiers during military campaigns (Felsen et al., 1945). Recently, during the Gulf War, 57% of the soldiers experienced an episode of diarrhea, and *Shigella* was isolated from 15% of the cases (Kotloff et al., 1999; Hyams et al., 1991).

Finally, increasingly in the developing world, an overlap is observed between zones of expanding HIV infection and endemic zones for shigellosis. Shigellosis in HIV-infected individuals shows more severe clinical patterns characterized by persistent or recurrent intestinal diseases as well as bacteremia (Angulo et al., 1995; Kristjansson et al., 1994).

Shigellosis in Developed Countries

Bacillary dysentery in industrialized countries is prominently associated with disadvantaged populations. Persons that exhibit poor personal hygiene, such as those living in custodial institutions, or preschool children and toddlers in day care centers, can experience epidemics of bacillary dysentery or sustained endemic transmission (Tauxe et al., 1990). Although estimates in industrialized countries are based on cases reported to the national reference centers, these may underestimate the real incidence. While death is a rare outcome in developed countries, morbidity remains high when outbreaks occur in custodial institutions and day care centers (Wennerås et al., 2000; Kotloff et al., 1999). *Shigella sonnei* is frequently associated with cases occurring in young children in schools and day care centers in industrialized countries (Pickering et al., 1981; Thomas et al., 1973; Vagn-Hansen et al., 1991; Mohle-Boetani et al., 1995). Large urban outbreaks also have been described following accidental contamination of a city water supply by sewage effluents (Egoz et al., 1991).

Distribution of Serogroups and Serotypes of *Shigella*

Shigella flexneri and *S. sonnei* account for the endemic form of shigellosis, whereas *S. dysenteriae* 1 accounts essentially for the epidemic form of the disease.

In developing countries, the most common *Shigella* species are *S. flexneri* (mainly serotypes 2a, 1b, 3a, 4a and 6) and *S. sonnei* (Kotloff et al., 1999). *Shigella dysenteriae* and *S. boydii* occur with equal frequency but *S. dysenteriae* type 1 is the most frequent cause of bacillary dysentery epidemics (Kotloff et al., 1999). *Shigella dysenteriae* 1 most often is identified in South Asia (Stoll et al., 1982; Khan et al., 1985) and sub-Saharan

Africa (Osisanya et al., 1988; Eko et al., 1991). It always has been distinguished by both its virulence and its ability to produce ravaging epidemics. *Shigella dysenteriae* 1 predominates in India (Stoll et al., 1982; Dutta et al., 1989), Malaysia (Jegathesan et al., 1984) and Guatemala (Ramiro Cruz et al., 1994), while type 2 predominates in Yemen (Al-Sallami et al., 1989) and Nigeria (Osisanya et al., 1988). *Shigella boydii* is uncommonly encountered except in the Indian subcontinent where it was first identified (Stoll et al., 1982; Dutta et al., 1989; Khan et al., 1985). In contrast, when the economy of a country improves, a switch occurs and epidemics usually are caused by *S. sonnei* (Kotloff et al., 1999). In the United States, the majority of bacillary dysentery cases are caused by *S. sonnei* infections. Among the *S. dysenteriae* isolated in the United States, types 1, 2 and 3 predominate. Serotype 2 predominates among *S. boydii* isolates (Bean et al., 1995). Limited data is available on serotypes isolated from travelers. In Finland, between 1985 and 1988, among 175 *Shigella* isolates from travelers, 75% were *S. sonnei*, 25% *S. flexneri*, 3% *S. boydii*, and less than 1% *S. dysenteriae* (Heikkilä et al., 1990). Similarly, among 235 strains isolated from Japanese travelers, 64% were *S. sonnei*, 25% *S. flexneri*, 8% *S. boydii* and 3% *S. dysenteriae* (Ueda et al., 1996). Recently, in the course of Operation Restore Hope in Somalia, the serotyping of 37 *Shigella* isolates yielded 23% *S. sonnei*, 43% *S. flexneri*, 19% *S. boydii* and 15% *S. dysenteriae* (Sharp et al., 1995). Among *Shigella* strains serotyped during the Gulf War, 81% were *S. sonnei*, 11% *S. flexneri*, 7% *S. boydii* and 4% *S. dysenteriae* (Hyams et al., 1991).

Pathogenicity

After oral inoculation, shigellae pass to the terminal ileum and colon where they invade and proliferate within epithelial cells, spreading from cell to cell. Bacillary dysentery is an invasive infection of the colonic and rectal mucosa that tends to remain local. In severe cases, the invasive process also may affect the terminal ileum. The disease process is characterized by an acute inflammation of the intestinal mucosa with ulcerations of the epithelium (Fig. 2). Why shigellae specifically invade the rectal and colonic mucosa is unknown. The bacteria rarely spread deeper in the lamina propria. Bacteremia occurs but is uncommon, except in malnourished children.

Models of Infection

The pathogenesis of *Shigella* can be studied in various animal models that variably reproduce the invasive and proinflammatory capacity of the

microorganism. The almost exclusive specificity of *Shigella* for humans explains the lack of an animal model that mimics the natural disease. Nevertheless, several model systems manifest different facets of *Shigella* enteropathogenicity. The keratoconjunctivitis assay or Sereny test (Sereny, 1957) reflects the capacity of *Shigella* to penetrate into the epithelial cells of the conjunctiva and to spread from cell to cell, including corneal cells, thus making the cornea turbid, following massive inflammation caused by the dispersion of bacteria in tissues. The Sereny test remains the test of reference to assess the invasive capacity of a *Shigella* isolate in spite of its lack of relevance to invasion of the intestinal barrier. Similarly, a mouse respiratory infection assay, in which intranasally inoculated invasive shigellae cause acute invasive tracheo-bronchitis and condensing alveolitis (Voino-Yasenetsky et al., 1961), is now often used to detect pathogenicity. Three assays are more relevant to the invasion of the epithelial barrier: 1) the starved guinea-pig model (LaBrec et al., 1961), which is mainly a paradigm of mucosal translocation and animal death following systemic dissemination of shigellae and septic shock; 2) the rabbit ligated intestinal (ileal) loop assay, which manifests the rupture of the intestinal barrier, invasion and tissue destruction, and also allows study of the role of the follicle-associated epithelium that covers mucosa-associated lymph nodes in epithelial translocation of *Shigella* (Wassef et al., 1989; Sansonetti, et al., 1996); and 3) the oral or intragastric infection of macaque monkeys, which is the only model allowing development of true bacillary dysentery (Honjo et al., 1964). The latter's high price and low sensitivity however restrict its universal use.

Over the last years, major efforts have been devoted to the development of cell assay systems, mostly using epithelial cell lines (Nakamura, 1967; LaBrec et al., 1964) or macrophages. These systems, although restricted to demonstration of cell invasion (Fig. 3) and cell killing, have allowed identification of most of the genes that are relevant to expression of the invasive phenotype of *Shigella*.

Natural History of the Disease

PATHOGENESIS DETERMINANTS OF *SHIGELLA*

Virulent *Shigella* isolates express an invasive phenotype whose expression depends on the type of cell that is invaded by the pathogen (Fig. 4). Invasive shigellae enter epithelial cells by inducing a massive but local reorganization of the cell subcortical cytoskeleton, which results in a micropinocytic vacuole (Clerc et al., 1987) that engulfs the microorganism (Fig. 5). Internalized bacteria quickly escape the phagocytic vacuole

and gain access to the cytoplasm in which they show rapid growth, as well as efficient actin-dependent intracellular motility and cell-to-cell spread (Makino et al., 1986; Bernardini et al., 1989). Simultaneously, the intracellular microorganisms reprogram infected epithelial cells to produce proinflammatory cytokines and chemokines (i.e., IL-8), essentially by inducing the translocation of NF- κ B into the nucleus (Philpott et al., 2000), thereby transforming these cells into efficient mediators of the innate immune response. In addition, in the presence of

lipopolysaccharide (LPS)-activated macrophages, invasive shigellae quickly cause apoptosis of these macrophages (Fig. 6) with concurrent release of massive quantities of the proinflammatory cytokine IL-1 β ; Zychlinsky et al., 1992; Zychlinsky et al., 1994). Invasive shigellae also induce increased adherence and release of the granular content of polymorphonuclear leukocytes (PMNs), thereby further aggravating inflammation (Renesto et al., 1996), even though shigellae are eventually killed by these PMNs (Mandic-Mulec et al., 1997).

GENES ENCODING THE INVASIVE PHENOTYPE

All virulent *Shigella* organisms harbor 200- to 230-kb plasmids collectively named the “virulent plasmid” (Hale et al., 1983), which were first described for *S. flexneri* 2a (Kopecko et al., 1980) and *S. sonnei* (Sansone et al., 1980). These plasmids contain the genes required to express the invasive phenotype (Parsot et al., 1999). It was established that the loss of the virulence plasmid results in avirulent strains (Sansone et al., 1982) and that the genes implicated in the virulent functions are localized not only in the virulent plasmid but also in the chromosome (Hale, 1991). This plasmid is the “toolbox” that establishes a connection between the bacterium and its target cell. A key factor is a type III secretin (Fig. 7) that delivers *Shigella* effector proteins straight from the bacterial cytoplasm into the target cell membrane and cytoplasm (Blocker et al., 2000; Fig. 8). The *mxi* and *spa* operons encode proteins that assemble into a flagellum-like structure. Upon contact of the bacterium with its target cell, about 15 proteins are secreted that can be divided into two categories. The first category encompasses invasion-related plasmid-encoded antigens (Ipa)B, C and D, which are essential to the initial events of bacterial invasion of epithelial cells (Ménard

Fig. 7. The 30-kb pathogenicity island of *S. flexneri* carried by the 220-kb virulence plasmid. Currently known functions of the gene products are shown.

Fig. 8. Schematic description of *Shigella* interaction with epithelial cells and macrophages via its Type III secretion.

et al., 1993). A complex formed by IpaB and IpaD controls the flux of Ipa proteins through type III secretion (Ménard et al., 1994). Then IpaB and IpaC form a complex that inserts into the eukaryotic cell membrane, thus generating formation of a pore that serves two purposes. One is to channel proteins into the target cell cytoplasm; the other is to cause actin polymerization via IpaC (Tran Van Nhieu et al., 1999) and apoptosis of target macrophages via IpaB (Chen et al., 1996). The IpaC-mediated actin polymerization and formation of the *Shigella* entry-focus involves recruitment and activation of the small GTPases of the Rho family: Cdc42, Rac and Rho (Adam et al., 1996; Watarai et al., 1997; Mounier et al., 1999). This signalling cascade is regulated by tyrosine kinase and the protooncogene *c-src* (Dehio et al., 1995; Dumenil et al., 2000). A second set of proteins secreted through the type III secretion encompasses two subgroups: IpaA and IpgD, which are constitutively expressed at 37°C, regardless of the activation of the secretion (Demers et al., 1998). The IpaA protein binds and activates vinculin, a protein that is physiologically present in cell adherence plaques and activates the cell's capacity for bundling actin filaments, as well as an unexpected capacity to depolymerize actin. It thus appears that IpaA is essential to the maturation of the entry focus as well as its disappearance (Bourdet-Sicard et al., 1999). Similarly, IpgD seems to be essential to the maturation of the

Shigella entry focus. Once bacteria have been internalized, they quickly lyse their phagocytic vacuole and escape into the cytoplasm where they grow very efficiently. Transcription of the genes encoding the secreted, type III-dependent proteins other than Ipa proteins and IpgD is dependent on the activation of the type III system. This is the case for a multigenic family: the IpaH genes.

OTHER *SHIGELLA*-PLASMID VIRULENCE-ASSOCIATED PROTEINS The type III secretion and its target proteins represent the principal effector of *Shigella* interaction with both epithelial and phagocytic cells. However, other proteins are encoded by the virulence plasmid that are not targets of the type III secretion. Among these proteins, SepA is an IgA-protease-like serine protease that enhances inflammation of infected tissues (Benjelloun-Touimi et al., 1995). However, intra- or intercellular spread (IcsA) protein/VirG emerges as one of the major effectors of *Shigella* virulence (Makino et al., 1986; Bernardini et al., 1989). This 120-kDa outer-membrane protein of *Shigella*, which localizes at one pole of the bacterial body, mediates actin-based motility of the bacteria as well as their cell-to-cell passage. This protein recruits and binds N-WASP, a member of the Wiscott-Aldrich family of proteins. Binding of N-WASP on IcsA activates its binding function to a potent actin nucleator Arp2/3. This is sufficient to cause actin nucleation/polymerization at the bacterial surface, thus causing bacterial motility (Egile et al., 1999) as illustrated in Fig. 9. Actin-based motility, in the context of a confluent, polarized epithelium, allows cell-to-cell spread in a process involving the engagement of the components of the cell junction (such as cadherins and their associated molecules) by the bacteria (Sansonetti et al., 1994). A protrusion is formed that is engulfed by the adjacent cell. The two membranes that surround the bacterial body are then lysed, thus allowing escape of the bacterium into the cytoplasm of the adjacent cell. Expression of IpaB and IpaC is essential for completion of this lytic process (Page et al., 1999; Maurelli et al., 1998). This cycle of cell infection, which is summarized in Fig. 10, is superbly efficient in promoting bacterial intracellular colonization of the epithelium. Mutants in which *icsA* has been deleted are severely affected in virulence when tested in macaque monkeys (Sansonetti et al., 1991) as well as in human volunteers (Coster et al., 1999).

CHROMOSOMAL VIRULENCE GENES These genes can be classified in two major categories. The first is genes that regulate virulence gene expression on the plasmid, such as *virR*, a master regulator

Fig. 9. In vitro assay: actin-dependent intracellular motility of *S. flexneri*. A) Actin comets trailing the moving bacteria. *Shigella* are stained in red with rhodamine-conjugated anti-LPS antiserum. Actin filaments are stained in green with FITC-phalloidin. Bar = 10 μ m. B) Transmission electron micrograph of actin nucleation and polymerization at *Shigella* surface revealed by decoration with S1 myosin. Bar = 1 μ m. that controls temperature-dependent expression of invasion genes (Maurelli et al., 1988) via its histone-like function (Dorman et al., 1990). The VirR protein directs a cascade of plasmid-encoded regulators such as VirF (which belongs to the AraC family; Sakai et al., 1986) and VirB (Tobe et al. 1991). The result is full expression of the invasive phenotype when bacteria are grown at 37°C and no invasion when bacteria are grown at 30°C. The second category comprises genes that are important for survival in the intestinal tract and in infected tissues such as those encoding the lipopolysaccharide and siderophores.

Fig. 10. Schematic representation of the major steps of epithelial invasion by *Shigella*.

Lipopolysaccharide. *Shigella* isolates that express a smooth LPS are virulent, whereas their rough mutants affected in expression of O-side chains are avirulent in in vivo assays such as the Sereny test. Also, LPS is the major constituent of the outer membrane. It has three covalently associated moieties: lipid A (responsible for the endotoxic activity of LPS), the core and O-side chains. The lipid A and core moieties are similar to their respective counterparts in *E. coli*. The O-side chains are composed of repeated sugar subunits that vary in their composition, thus accounting for the serotype diversity. In *S. flexneri* (Fig. 1), O-side chains are composed of a basic tetrasaccharide subunit constituting the serotype Y. Composition of this basic polysaccharide is 3β -N-acetyl-glucosamine- α 1-2-rhamnose- α 1-2-rhamnose- α 1-3-rhamnose-1. Serotype variations, also called “serotype conversions,” are then conferred by temperate bacteriophages that carry glucosyl-transferases or acetyl-transferases that add glucosyl or O-acetyl groups to different sugars in the tetrasaccharide subunit (Allison et al., 2000). This provides the conversions leading to serotypes 1–5. *Shigella flexneri* serotype 6 remains an exception to this rule (Simmons et al., 1987). The principle of serotype variation in *S. flexneri* explains the frequent crossreactivity observed between those serotypes. Conversely, *S. sonnei*, whose genes encoding LPS O-side chains are located on the large virulence plasmid, presents a single—phase I—serotype, which is lost upon the loss of the virulence plasmid, thus leaving rough—phase II—clones (Sansonettil et al., 1980). In *S. dysen-*

teriae 1, the LPS-biosynthesis genes are located both on the chromosome and on a 9-kb plasmid (Watanabe et al., 1984).

When complementing an *E. coli* K₁₂ recipient by successive introduction of the *S. flexneri* virulence plasmid and chromosomal sequences from the same donor, expression of a smooth LPS appeared essential for transformants to express full virulence in in vivo assays such as the Sereny test and the rabbit ligated intestinal loop model (Sansonetti et al., 1983). Although rough strains are able to invade in vitro-cultured cells, they are impaired in their capacity to spread from cell to cell. This may be related to an indirect effect of the lack of O-side chains on the proper polar localization of IcsA, thereby altering actin-driven motility and cell-to-cell spread (Sandling et al., 1995). In addition, rough mutants of *Shigella* are hypersensitive to serum killing, and this sensitivity likely accounts for the lack of survival in inflamed tissues (Rowley, 1968).

Iron Chelation. Other virulence factors encoded by the chromosome of *Shigella* include siderophores and their surface receptors. Siderophores are low-molecular weight molecules with high affinity for ferric iron for which they compete against physiological carriers such as transferrin and lactoferrin. Most isolates of *S. flexneri* and *S. sonnei* express aerobactin siderophores, whereas, *S. dysenteriae* and some *S. sonnei* isolates express enterochelin receptors. Aerobactin-deficient mutants of *S. flexneri* are impaired in their capacity to grow in infected tissues (Nassif et al., 1987).

Shiga Toxin. In addition to the well-established virulence factors encoded by the chromosome in *S. dysenteriae* 1, Shiga toxin is encoded by a chromosomal gene designated “*stx*,” which maps near *pyrF*, at centisome 28 (Sekizaki et al., 1987; O’Brien et al., 1992). High levels of iron and reduced temperature repress production of Shiga toxin; iron regulation is governed by the ferric uptake regulator (Fur; O’Brien et al., 1987; Weinstein et al., 1988). Shiga toxin is a heterodimer that exerts potent cytotoxicity causing cell death by blocking eukaryotic protein biosynthesis. It shows a StxA(1)/StxB(5) stoichiometry. The StxA protein carries the catalytic activity, whereas StxB accounts for the binding of the toxin to Gb₃, its ganglioside receptor molecule (Keusch and Jacewicz, 1977). Once internalized via receptor-mediated endocytosis in polarized epithelial cells, Shiga toxin reaches the Golgi apparatus from which StxA crosses the membrane and reaches the cytosol (Sandvig et al., 1991). A highly specific N-glycosidase, StxA removes adenine from one particular adenosine residue in the 28S RNA of the 60S ribosomal subunit of the eukaryotic cell target (Endo et al., 1988). This mode of action leads to arrest of pro-

tein biosynthesis, and cell death is strictly similar to that caused by plant toxins such as ricin and abrin (Saxena et al., 1989).

The function of Shiga toxin in eliciting diarrhea in the case of *S. dysenteriae* 1 infection has not yet been convincingly demonstrated in humans, although its enterotoxicity is clear in the rabbit ligated loop model (Butler et al., 1986). As the Gb₃ receptor for Shiga toxin is essentially detected in the non-epithelial fractions of intestinal tissues, it is possible that this toxin aims largely at non-epithelial targets in the intestinal mucosa and also may act systemically. Evidence indicates that Shiga toxin may primarily behave as a toxin for the vascular endothelium. Epidemiological data indicate that patients infected with *S. dysenteriae* 1 have more blood in their stools than patients infected with other species of *Shigella* (Stoll et al., 1982). In addition, macaque monkeys infected intragastrically with a wild-type isolate of *S. dysenteriae* 1 showed massive presence of blood in their stools, as well as major vascular destruction (particularly of capillaries of the lamina propria) in their intestinal tissues, compared to animals infected with a StxA-mutant, which showed less blood and limited vascular destruction (Fontaine et al., 1988). Some systemic manifestations also may be caused by Shiga toxin. This is particularly the case for the hemolytic uremic syndrome (HUS). Although the pathogenesis of this often fatal disease is not yet understood, its observation following infection with *S. dysenteriae* 1 and enterohemorrhagic strains of *E. coli* (EHEC) that produce Shiga-like toxins is a strong indication of a direct link. Histopathological analysis shows kidney lesions that are dominated by thrombosis and destruction of the glomerular capillaries, and sometimes cortical necrosis (Koster et al., 1978). The Gb₃ receptor is found in high density on human kidney endothelial cells, which are exquisitely sensitive to Shiga toxin (Obrig et al., 1993).

Shigella produces toxins other than Shiga toxin. Two enterotoxins have been described that may account for the early diarrheal phase often observed in the course of shigellosis. *Shigella* enterotoxin 1 is a chromosomally encoded toxin of 55 kDa that is essentially expressed by *S. flexneri* 2a (Noriega et al., 1995), and *Shigella* enterotoxin 2 is a plasmid-encoded enterotoxin of 63 kDa (Nataro et al., 1995).

Other potentially important components of virulence determination are chromosomal “black holes” (Maurelli et al., 1998), which correspond to genes that are deleted or not expressed, because their otherwise expressed product would alter virulence. This is the case for the *cad* gene encoding lysine-decarboxylase (LDC) function and the former *kcpA* gene

(keratoconjunctivitis production), which actually corresponds to the elimination of a lysogenic phage encoding a surface outer-membrane protein, OmpT. If expressed, this protease would cleave off the entire pool of surface-expressed IcsA, thereby leading to a phenotypically IcsA⁻, nonmotile, mutant (Formal et al., 1971).

INTEGRATION OF PHENOTYPES Shigellosis is prototypical of an infectious disease in which the pathogen manipulates innate immunity, particularly the inflammatory response, to disrupt and invade the intestinal mucosa. Severe intestinal tissue destruction may be the high cost that the host needs to pay to ensure bacterial eradication after a primary infection. Before eliciting this response, *Shigella* must cross the epithelial barrier, a process that can hardly be achieved through the apical pole of epithelial cells (Mounier et al., 1992; Perdomo et al., 1994a). Current evidence indicates that the initial entry route is through the follicle-associated epithelium (FAE) that overlays the lymphoid follicles associated with the intestinal mucosa, particularly those disseminated in the colonic and rectal mucosa (Sansone et al., 1999b). M-cells (essential functional components of the FAE) provide the initial route of bacterial translocation through the epithelium. These M-cells lack mucus and glycocalyx on their apical surface. They also are devoid of brush border microvilli. Consequently, this apical surface is easily accessible to pathogenic microorganisms of the intestinal lumen, and the high transcytotic activity of these cells facilitates translocation of the microbes through the epithelial lining straight into the inductive sites of mucosal immunity. M-cells form a pocket filled with both lymphocytes and resident macrophages (Neutra et al., 1996), thus providing direct contact between the intestinal flora and the mucosal-associated immune system (MALT). Selection of this route, which facilitates trans-epithelial translocation, however, directs the pathogenic microbe into an aggressive environment—the follicular dome—characterized by the density of resident macrophages. To survive, an invasive microorganism must evade the killing mechanisms of those phagocytic cells. Causing apoptotic death of its phagocytic macrophage seems to be the survival strategy that *Shigella* has selected (Zychlinsky et al., 1992; Zychlinsky et al., 1992). The secreted invasin IpaB of *Shigella* activates caspase 1 (a cysteine protease), which under these circumstances is able to induce the apoptotic cascade and proceed to rapid macrophage killing both in vitro and in vivo (Zychlinsky et al., 1996). Simultaneously, caspase 1 activation leads to the proteolytic cleavage of proIL-1 β , thereby allowing for the release of mature IL-1 β (Hilbi et al.,

1998), a potent proinflammatory cytokine that appears to be central in initiating mucosal inflammation in shigellosis (Sansone et al., 1995). This sequence of events causes a paradigm of “M-cell translocation—macrophage apoptosis—induction of inflammation,” which appears to be characteristic of the early stage of shigellosis. The concurrent decrease in IL-1RA, a non-agonistic competitor of IL-1 for its receptor, contributes to the inflammatory process (Sansone et al., 1999b). Simultaneously, caspase 1 activation also causes the proteolytic cleavage of IL-18, another proinflammatory cytokine, which is also a potent inducer of interferon γ (Fantuzzi et al., 1998), a cytokine that has been shown to be essential for the control of *Shigella* infection (Way et al., 1998). This concurrent event seems to be essential for the programming of the host antibacterial effect (Sansone et al., 2000). This is an example of the subtle balance that controls an infectious process. How could this benefit the microbe? It is actually paradoxical that such response does not lead to the immediate eradication of the invading pathogen. A combination of in vitro and in vivo experiments (Perdomo et al., 1994a; Perdomo et al., 1994b) have established another paradigm, also called “fatal attraction” in which the early inflammation serves as a “Trojan horse” for invasive shigellae. Inflammation that can be aggravated by a trans-epithelial signalling process disrupts the permeability of the epithelial barrier via induced transmigration of inflammatory cells, particularly polymorphonuclear leukocytes (PMNs), thereby allowing access of bacteria to the basolateral pole of epithelial cells, which is permissive to bacterial entry. Here, the invasive phenotype of *Shigella* takes full significance because penetration of bacteria into epithelial cells, as well as cell-to-cell spread, allows protection and diffusion of the microbe. As shown in Fig. 11, one can establish a scheme in which early entry at follicular sites followed by inflammation leads to centrifugal progression via the combined effect of inflammatory disruption of the epithelial barrier and epithelial cell invasion and cell-to-cell spread. In addition, IL-8 produced by infected epithelial cells causes massive attraction of PMNs that, at the cost of epithelial destruction, actively participate in the protection against bacterial translocation, mucosal diffusion, and systemic dissemination (Sansone et al., 1999b).

Microbial Diagnosis

The diagnosis of shigellosis depends mainly on microbiological examination. For epidemiological studies, immunological assays for antibodies to *Shigella* LPS represent an alternative method

Fig. 11. Schematic representation of the crossing, rupture, invasion and inflammatory destruction of the intestinal barrier by *Shigella*.

to diagnose *Shigella* infection in retrospect (Lindberg et al., 1991; Cam et al., 1993). Bacteriological methods for isolation of *Shigella* from feces are widely available. *Shigella* are present in the feces of patients in concentrations ranging from 10^3 – 10^9 viable bacteria per gram during the acute phase of the disease, but they readily die off if the stool sample is not well processed. *Shigella* may not survive changes in pH (acidification) owing to the growth of other bacteria or to a decrease of the temperature. *Shigella* are more fastidious and difficult to cultivate at later stages of the illness.

Specimen Collection and Transport Media

To increase chances of successful isolation of *Shigella*, the specimens of choice are (in order of decreasing productivity) rectal swab specimens, fresh stools, and anal swabs collected during the active stage of the disease (Echeverria et al., 1991) before any antibiotic has been taken. Streaks of blood, mucus and pus, which are characteristic of dysenteric stools, should be cultured as they are likely to contain a dense population of almost pure *Shigella*. Once collected, these specimens should ideally be immediately inoculated onto culture media, as *Shigella* may not survive changes of pH resulting from overgrowth of other bacteria, or from a drop in temperature. If a delay in transporting stool or swab specimens is expected, direct inoculation into buffered glycerol saline (BGS), with an indicator to control the pH during transportation, is essential. Refrigerated BGS preserves *Shigella* better than the Cary-Blair transport medium. After inoculation, this transport medium should be used for plating on isolation media as quickly as possible (within 6 h).

Isolation of *Shigella*

There is no effective and reliable enrichment procedure to ensure accurate determination of the presence of *Shigella* in feces, food or environmental samples. If the collection and handling of the specimens have been properly done, direct plating is therefore enough for successful isolation. Ideally, several media should be used to increase chances of isolation: one medium of low selectivity (i.e., MacConkey or Eosin-Methylene Blue [EMB] agar), one medium of high selectivity (i.e., Hektoen, *Salmonella-Shigella* [SS] or Xylose-Lysine-Deoxycholate [XLD] agar), and one nonselective medium (Bromocresol-Purple agar Lactose [BCP]). The choice of an optimal medium for primary culture of stool samples depends on the local conditions of work, on the prevalent strains in a region, and on the microbiologist's own experience. When working in the field, SS medium has the advantage of not requiring autoclaving, but is not adapted for *S. dysenteriae* type 1 and *S. sonnei* whose isolation is facilitated by the use of tergitol-7-tetrazolium agar. MacConkey and BCP agar plates appear to be the best media.

To optimize chances of recovering the very low numbers of *Shigella* found in some feces specimens, a portion of stool specimen may be inoculated into an enteric enrichment broth, such as Gram-negative broth, before plating onto the agar medium.

Identification of *Shigella*

Shigella are non-lactose-fermenting enterobacteria. After 12–15 h of incubation of agar plates at 37°C, positive colonies that appear in positive cases will be selected for further examination. Such colonies may be subcultured on a more selective medium before complete identification. On MacConkey, Hektoen, BCP and SS agar, colonies appear translucent, and convex, with a smooth surface and a diameter between 0.5 and 1 mm. Suspect colonies can be identified directly in many commercial identification systems. In routine work, these colonies can be screened for *Shigella* genus by subculturing onto differential media to be distinguished from the other genera of the family Enterobacteriaceae. On Kligler-Iron-Agar (KIA), isolates that are glucose positive (acid yellow butt), lactose negative (alkaline red slant), H_2S negative, gas negative, and non-motile on Motility-Indole-Urea (MIU) agar, can be further identified to genus and species. The four species of *Shigella* can be differentiated by biochemical properties (Table 1). *Shigella* are typically non-gas producing, with the exception of *S. flexneri* 6, *S. boydii* 13 and 14, and *S. dysenteriae* 3, all of which produce gas from glucose.

The four species are lysine decarboxylase⁻, acetate⁻, mucate⁻. Only *S. sonnei* ferments lactose slowly and ferments mucate, and some isolates can decarboxylate ornithine. Strains of *S. dysenteriae* are always negative for mannitol fermentation, are also catalase negative and occasionally *o*-nitrophenyl- β -D-galactopyranoside (ONPG) positive. *Shigella* species appear biochemically very similar, and differentiation among species depends on serological methods. In practice, serological methods using group- and type-specific antisera must be performed only after biochemical presumptive identification of *Shigella* species.

One can propose the following simple scheme for biochemical identification of *Shigella*:

Isolates are nonmotile and LDC negative;

With the few above-mentioned exceptions, isolates do not produce gas during carbohydrate fermentation.

Isolates fermenting mucate, or those alkaline on acetate or on Christensen's citrate agar, are likely to be *E. coli*.

Following this simple scheme, sero-agglutination should be performed.

Serogrouping of *Shigella* Isolates

Although *Shigella* species can be identified presumptively at the genus level with biochemical tests as described above, their identity must be confirmed in slide agglutination with polyvalent (serogroups A–D) antisera. Agglutinating isolates suspected to be *Shigella* would then be tested by slide agglutination with monovalent, O-specific (serogrouping) antisera to identify the serogroup of a *Shigella* species. Below the species level, serotyping is usually done in reference laboratories. *Shigella* serotyping occasionally is affected by the transition from the smooth (S) form to the rough (R) form, and several intra- and interspecific crossreactions have been reported to interfere with the serotyping assay. The identification of *Shigella* serotypes by restriction of amplified O-antigen gene cluster was developed by Coimbra et al. (1999).

Differentiation of *Shigella* spp. and *Escherichia coli*

Shigella spp. closely resemble *Escherichia coli* at the genetic level, and the biochemical identification sometimes requires additional tests (Table 1). Non-lactose-fermenting or anaerogenic strains of *E. coli* can be differentiated from *Shigella* by the following biochemical tests: Christensen's citrate, fermentation of sodium acetate and mucate, and decarboxylation of lysine. *Shigella* spp. are negative for these tests. When biochemically identified isolates of *Shigella* do not

agglutinate in *Shigella* antisera, a bacterial suspension should be heated (100°C for 15 min) and tested again for agglutination. In case of persistently negative agglutination, such isolates could correspond to enteroinvasive *E. coli* (EIEC) and should be sent to a reference laboratory for testing. The EIEC closely resemble *Shigella*; they are often lactose negative, lysine decarboxylase negative, and nonmotile (except for the O124 serogroup).

Preservation of Cultures

Cultures of *Shigella* can be preserved for several years by conservation in Dorset egg agar or in cooked meat medium at room temperature. They also can be maintained either lyophilized or frozen at -80°C or in liquid nitrogen for very long periods. However, whatever conservation technique is selected, avirulent variants often arise owing to the loss or deletion of large fragments of the virulence plasmid. When reisolating a strain from a stock, care must therefore be taken to avoid reisolating and subculturing an avirulent (i.e., noninvasive) clone. Addition of Congo red to the agar medium allows identification of potentially invasive colonies (i.e., Congo red positive) that appear small, smooth, convex, and with a red central area of Congo red accumulation (i.e., rabbit-eye-like colonies), whereas noninvasive colonies (i.e., Congo red negative) appear large, flat and white, owing to an inability to accumulate the Congo red. In case of persisting doubt, colonies should be tested in an in vitro assay of invasion (i.e., invasion of cultured eukaryotic cells) or in the Sereny test.

Molecular Diagnosis

Several key determinants involved in the pathogenicity of *Shigella* species and EIEC are plasmid- and chromosome-mediated. Investigators have developed DNA probes to diagnose and differentiate *Shigella* and EIEC from other non-pathogenic stool flora (review by Tenover et al., 1989).

Polymerase chain reaction (PCR) techniques applied to diarrheal stools (Luscher et al., 1994; Frankel et al., 1990; Achi et al., 1996) and food (Bef et al., 1991; Lindqvist et al., 1999; Villalobo et al., 1998) may be considered a more sensitive and specific technique than the conventional culture technique. The use of PCR to amplify a specific *virA* gene fragment (Villalobo et al., 1998) or the invasion plasmid antigen H (*ipaH*) DNA sequence (a multiple copy sequence found on the chromosome and the invasion plasmid; Sethabutr et al., 1993; Gaudio et al., 1997) serves as a specific and sensitive method to detect virulent bacteria of the genus *Shigella* and EIEC, and

has the potential to be employed in routine diagnosis of dysentery in clinical centers (Islam et al., 1998). Several methods, such as nested PCR amplifying sequences with an invasion-associated locus (*ial*; Lindqvist et al., 1999), multiplex PCR assay (Villalobo et al., 1998; Oyofu et al., 1996), immunomagnetic separation-PCR assay (Achi et al., 1996; Islam et al., 1992), and automated methods of identifying PCR products (PCR-ELISA; Sethabutr et al., 2000) that process large numbers of specimens, facilitate epidemiological studies. A simple PCR procedure using IS 630-specific primers was developed as a general diagnostic probe to detect *Shigella* and EIEC (Houng et al., 1997). However, IS 630, *ipaH* and *ial* cannot be used to differentiate among *Shigella* serotypes and EIEC that cause dysentery. Serotype-specific primers derived from the *rfc* genes can differentiate among *Shigella* serotypes (such as *S. sonnei*, *S. flexneri* and *S. dysenteriae* 1) in the laboratory, and the multiplex PCR system containing *rfc*-specific primers can efficiently identify the most prominent *Shigella* serotypes in raw stool samples of diarrheal patients (Houng et al., 1997).

Treatment of and Antibiotic Resistance to Shigellosis

Oral rehydration therapy provides little benefit to patients with dysentery and anti-diarrheal drugs, which decrease intestinal motility, may worsen bacillary dysentery, and should not be used in those circumstances (Wennerås et al., 2000; DuPont et al., 1973). In addition, the successful implementation of oral rehydration therapy in the developing world has increased the relative importance of dysentery and persistent diarrhea as a cause of mortality and morbidity in children (Khan et al., 1985). In a study carried out in Bangladesh, deaths attributed to dysentery among children 1–4 years outnumbered deaths attributed to watery diarrhea by a factor ranging between 2.1 and 7.8 (Bennish et al., 1991).

Antibiotics, on the other hand, shorten the duration of dysentery and bacterial excretion in stools (Haltalin et al., 1972). Although most cases of shigellosis are self-limiting and clinically benign, thus raising some controversy about the need to provide systematic antibiotic treatment, antimicrobial treatment is usually prescribed, particularly in severe cases. Unfortunately, over the years, multiresistant *Shigella* strains have become very common (Sack et al., 1997). *Shigella* quickly acquired plasmid-encoded resistance to the antimicrobial drugs that constituted first-line therapy. Throughout the world, *Shigella* isolates now express resistance to sulfonamides, trimethoprim-sulfonamides, tetracycline, ampi-

cillin, chloramphenicol and streptomycin. The *S. dysenteriae* type 1 strain that was responsible for the devastating outbreak in the former Zaïre among Rwandan refugees was resistant to all the commonly used antibiotics (Goma Epidemiology Group, 1995). In industrialized countries, multiresistant *Shigella* infections can be treated with a third-generation cephalosporin or a new 4-fluoroquinolone (Bennish et al., 1990b), but few reliable options exist in developing countries where the cost and practicality are paramount considerations. In these countries, nalidixic acid (first-generation quinolone) remains a valuable alternative (Germani et al., 1998b).

Travelers are infected with multiresistant *Shigella* with increasing frequency (Heikkila et al., 1990; Tauxe et al., 1990). Recent data from the National *Shigella* Reference Center in Finland (Heikkila et al., 1990) showed that 98% of strains isolated from travelers were resistant to trimethoprim, whereas only 3% of the strains were resistant to this antibiotic before 1975. In the United States, among domestically acquired isolates, only 5% are resistant to trimethoprim-sulfamethoxazole and 10% to ampicillin, whereas among isolates collected from travelers, nearly 20% are resistant to trimethoprim-sulfamethoxazole and 60% to ampicillin (Tauxe et al., 1990). During operation Desert Shield/Storm in the Arabian Peninsula (Hyams et al., 1991), 85% of the *Shigella* strains tested were resistant to trimethoprim-sulfamethoxazole. Among strains isolated from soldiers in the operation in Somalia in 1995 (Sharp et al., 1995), a high level of resistance to doxycycline, ampicillin and trimethoprim-sulfamethoxazole was reported.

The suggestion to reserve antibiotic treatment to the most severe cases of shigellosis is also a matter of debate (Wennerås et al., 2000; Weissman et al., 1973). A reason to limit the use of antibiotics in this case is that they have been implicated in the development of the hemolytic uremic syndrome (Butler et al., 1987). This seems to be unlikely, as the most severely affected patients are the most likely to both receive antibiotics and develop severe systemic complications.

Specific Immune Response Against *Shigella* Infection

Most of our knowledge of the specific (adaptive) immune response against *Shigella* has been collected from observations in humans. Evidence indicates that *Shigella* infection confers protective immunity, although its mechanisms are not fully understood. Among the evidence is the fact that shigellosis peaks during the first five years

of life and subsequently declines, suggesting that immunity occurs following repeated exposures to *Shigella* during childhood (Taylor et al., 1986). Also, the incidence of the disease decreases with the duration of stay in an endemic setting (Cohen et al., 1992). Following *Shigella* infection, protection against the homologous serotype is established (DuPont et al., 1972). This suggested that LPS was the major target of protection and that the humoral, likely local, immunity was the major effector. Strong evidence for serotype-specific natural immunity was provided by a study in Chilean children in whom the primary *Shigella* infection conferred 76% protective efficacy against reinfection with a homologous serotype (Ferrecchio et al., 1991). Serum and stool antibody levels of anti-*Shigella* LPS and Ipa proteins have been detected following natural infection and infection in volunteers (Cam et al., 1993; Islam et al., 1995; Oberhelam et al., 1991; Cohen, et al., 1989). Specific anti-LPS IgA antibodies in stool samples peak within 5–10 days of infection and may participate in resolution of infection, taking over the attempt of the innate response to eradicate shigellae (Cam et al., 1993). In parallel, increasing levels of serum anti-LPS IgG and IgA also are observed. Stool and serum IgA levels then fall rapidly to background level within 2–3 months. People living in areas where shigellosis is endemic have higher background serum IgG levels and mount greater serum IgG response than infected people living in nonendemic areas. On the other hand, mucosal IgA levels appearing in response to infection are similar in both groups. These results suggest that a systemic IgG memory response exists, whereas the mucosal IgA memory response is of relatively short duration.

The murine pulmonary model of shigellosis also has been used to study the specific immune response, although the local IgA and IgG responses against LPS and Ipa proteins following a sublethal infection are slow to develop and need a second challenge (Van De Verg et al., 1995). Short-lived serotype-specific protection nevertheless was demonstrated in this model; although IgM seemed to be predominantly involved, T-cell mediated protection did not seem to play a role. This model also has been used to demonstrate that anti-LPS IgA can protect against challenge with a lethal dose of *Shigella* (Phalipon et al., 1995).

In summary, protective immunity seems to be essentially dependent on a local humoral response against LPS, although this local immune memory appears short lived compared to the serum IgG response whose actual protective capacity is neither sufficiently evaluated nor clearly explained. In addition, although it is difficult to believe that an infection that has a clear

intracellular stage does not involve a strong protective T-cell component, the actual function of cellular immunity in shigellosis remains unknown.

Prevention of *Shigella* Infections

Because the only significant source of *Shigella* infection is infected humans and the transmission most often is oro-fecal, sanitary measures are essential for disease prevention. These measures should include hand washing with soap, chlorination of water, proper disposal of feces, and protection of food from contamination, particularly by flies. Patients, particularly those preparing foods, should be isolated ideally until their stool cultures have become negative. Proper antibiotherapy, which shortens the duration of *Shigella* excretion, also may help decrease the spread. However, control may not be easy in the most impoverished regions in which the disease is endemic, or in emergency situations (i.e., constitution of refugee camps) where implementation of proper personal and general hygiene standards is difficult. This may be complicated by the high incidence of unapparent infections in such situations and the low inoculum of shigellae, which is required to elicit the disease. These considerations, added to the increased resistance to antibiotics, have led to consideration of vaccination against shigellosis as an efficient and cost-effective approach for prevention.

Toward Vaccine Prevention

Considering that the protective immunity against *Shigella* infection is essentially serotype-specific, the protective capacity of any *Shigella* vaccine candidate will depend greatly on the representation of serotypes incorporated in the vaccine and the epidemiological importance of these respective serotypes in the area. This emphasizes the need for evaluation of the disease burden and of the representation of serotypes in any area where such vaccine candidates are to be studied (Clemens et al., 1999).

Initial attempts at immunizing against shigellosis were based on whole-cell killed preparations administered parenterally. The complete failure that followed this approach led to the concept that parenteral immunization could not successfully protect against shigellosis. For a disease that remained local, mucosal immunization with live attenuated oral vaccine candidates was a better option. Initial attempts in the mid-sixties using multiple oral doses of streptomycin-dependent (SmD) strains provided very encouraging results and also indicated that the

protection that could be achieved was serotype-dependent (Mel et al., 1965). In addition to the preparation of subcellular vaccines such as proteosomes and ribosomes, which still need to demonstrate protective capacity in humans, two major approaches have been investigated recently with encouraging results (Sansonetti, 1998).

A subunit parenteral vaccine composed of purified/detoxified *S. sonnei* LPS conjugated with a toxoid has shown about 70% homologous protection in the course of a *S. sonnei* outbreak in the Israeli Army (Cohen et al., 1996). Unlike killed whole-cell vaccines, these polysaccharidic conjugates elicit high anti-polysaccharide IgG titers that may protect via diffusion through the colonic epithelial barrier.

Alternatively, different groups have engineered several live-attenuated vaccine candidates. Attenuation strategies are based on the deletion of gene(s) involved in encoding key enzymes of metabolic pathways that are essential for bacterial survival in tissues (i.e., mutations in *aro* genes or *guaB*, A genes) and/or pathogenicity genes that are essential for the bacterium to proceed to a key step of its pathogenic program (i.e., the *icsA* gene). So far, a *S. flexneri* 2a mutant (SC602) that has undergone a deletion in both *icsA* and *iuc* (the operon encoding the Fe³⁺ chelator aerobactin) has been shown to be protective after a single oral dose against a homologous virulence strain in a challenge study in volunteers (Coster et al., 1999). Further studies are going on in endemic areas. Similar strains have been constructed in *S. dysenteriae* 1 and *S. sonnei*.

Acknowledgments. PS would like to dedicate this chapter to his two mentors Samuel B. Formal and Léon Le Minor for their outstanding contributions to the field of Enterobacteriaceae.

The Genus *Salmonella*

CRAIG D. ELLERMEIER AND JAMES M. SLAUCH

Introduction and History

The *Salmonella* live in the intestines of animals and have evolved with their hosts (see Phylogeny). Thus, *Salmonella* infection is an ancient disease, and typhoid fever has been well described throughout written history (Cunha, 2004). However, confusion between the diseases typhus and typhoid existed until the mid-1800s, even though previous investigators had differentiated the two (Miller and Pegues, 2000; Cunha, 2004). For example, Oxford physician Thomas Willis (1621–1675), in 1659, noted the ileal ulcers associated with typhoid. With the increasing use of autopsies, in the 1820s, Pierre Bretonneau (1778–1862) and colleagues described that the Peyer's patches were inflamed in typhoid. He also noted that the disease was contagious and that once a person survived typhoid, they did not get the disease again. French physician Pierre Charles Alexandre Louis (1787–1872) first used the term “typhoid fever” in 1829. William Jenner (1815–1898) further clarified the differences between typhus and typhoid based on symptomology and, importantly, epidemiology in 1850; the fact that he personally suffered from both diseases strengthened his differential diagnosis. William Budd (1811–1880) concluded in 1873 that typhoid fever was spread by the fecal-oral route. Karl Eberth (1835–1926) observed in 1880 rod-shaped organisms in the spleens and lymph nodes of typhoid patients and is credited with discovering the serovar Typhi organism. Georg Gaffky (1850–1918) first successfully cultured serovar Typhi from patients in Germany in 1884. In 1885, Theobald Smith (1859–1934), working under American veterinarian Daniel E. Salmon (1850–1914), isolated what became known as *Salmonella choleraesuis* from the intestine of a pig. French bacteriologist Joseph Léon Marcel Lignières (1868–1933) suggested in 1900 that the group of bacteria represented by the swine-cholera organism should be termed “*Salmonella*” in honor of Salmon. Georges Widai (1862–1929) in 1896 coined the term “agglutinin” to describe the clumping of heat-killed serovar Typhi cells by convalescent serum (the Widal reaction).

Almroth Edward Wright (1861–1947) and, independently, Richard F.J. Pfeiffer (1858–1945) and Wilhelm Kolle (1868–1935), used heat-killed organisms to vaccinate against typhoid in 1896; essentially the same vaccine is still in use today (see Serovars Typhi and Paratyphi). Elie Metchnikov (1845–1916) fulfilled Koch's postulates to prove that serovar Typhi caused typhoid in 1911. Fritz Kauffmann (1899–1978), extending the work of P.B. White (White, 1926), established serological analysis of *Salmonella* starting in the 1940s. In 1948, Theodore E. Woodward (1914–) and colleagues successfully treated patients in Malaysia with chloromycetin (chloramphenicol).

Serovar Typhimurium strains became a favorite tool of the burgeoning number of bacterial geneticists. In 1948, K. Lilleengen characterized a series of 25 clinical isolates representing different phage sensitivities (see Phage Typing). He designated these strains “Lilleengen Type” or LT1 through LT25 (Lilleengen, 1948). Serovar Typhimurium strain LT2 is now the type strain (see Taxonomy) and the complete genome has been sequenced (McClelland et al., 2001). Norton D. Zinder (1928–) and Joshua Lederberg (1925–) used the LT strains to study genetic exchange, leading to the discovery in 1952 of bacteriophage-mediated transduction (Zinder and Lederberg, 1952). The phage in question was P22 (isolated from LT22), the workhorse of *Salmonella* genetics. Milislav Demerec (1895–1966) obtained the LT strains from Zinder and began a series of genetic studies. The resulting LT2 (and LT7) derivatives are still being characterized (Rabsch et al., 2004). Indeed, LT2 rivals *Escherichia coli* K12 as an object of genetic analysis (see <http://www.ecosal.org>). This chapter covers aspects of the *Salmonella* genus, mainly recent studies and recent reviews of the major topics. The reader is directed to these reviews and the references therein.

Phylogeny

Salmonella are members of the Enterobacteriaceae, in the Gamma-proteobacteria subdivi-

sion. Two species of *Salmonella* are recognized: *Salmonella bongori* and *Salmonella enterica*. *Salmonella enterica* can be further divided into seven subspecies on the basis of biochemical characteristics (biotype), differences observed in multilocus enzyme electrophoresis (MLEE), phylogenetic analysis using 16S rRNA or other sequences, or analyses using other molecular techniques such as amplified-fragment length polymorphism (AFLP; Selander et al., 1996). Members of *S. enterica* subsp. I account for 99% of all human infections. Molecular analyses of *Salmonella* have been facilitated by the existence of the “*Salmonella* reference collections” (available from the *Salmonella* Genetic Stock Center). *Salmonella* reference collection A (SARA) contains 72 strains from a variety of environments and hosts (Beltran et al., 1991). SARB consists of 72 strains of *S. enterica* subsp. I (Boyd et al., 1993), while SARC contains two strains of *S. bongori* and two strains from each of the seven subspecies of *S. enterica* (Boyd et al., 1996). Strains in all three collections have been well characterized by Selander and colleagues using MLEE.

The availability of complete genomic sequences (McClelland et al., 2001; Parkhill et al., 2001) has significantly increased our understanding of the evolution of *Salmonella* and their relation to other members of the Enterobacteriaceae. McClelland and colleagues compared the genetic content of strains in the SARC collection and other representatives of the Enterobacteriaceae by direct probing of a *Salmonella enterica* serovar Typhimurium strain LT2 open reading frame (ORF) microarray with genomic DNA from the strain of interest, or comparison of completed genomic sequences (Porwollik et al., 2002). The overall results of this analysis in the form of a phylogenetic tree are presented in Fig. 1. Consistent with previous studies (Baumler et al., 1998), these data suggest that the evolution of *Salmonella* has been largely dictated by the acquisition of horizontally transferred segments of DNA, or islands, encoding virulence factors that have allowed the new subspecies to colonize a different niche.

A general model for the evolutionary history of the genus, delineated by a variety of investigators (Selander et al., 1996; Baumler et al., 1998; Edwards et al., 2002; Porwollik et al., 2002; Chan et al., 2003) can be summarized as follows (Fig. 1). *Salmonella* and *E. coli* diverged 120–160 million years ago, about the time that mammals first appeared. Approximately 25–40 million years ago, the common *Salmonella* ancestor acquired the *Salmonella* pathogenicity island 1 (SPI1) which encodes a type III secretion system involved in invasion of the intestinal epithelium (see SPI1 TTSS). Thus, *Salmonella* became an

Fig. 1. Model for the evolution of *Salmonella*. 1) The common *Salmonella* ancestor acquired the SPI1 type III secretion system (TTSS) allowing intestinal invasion. 2) The two species of *Salmonella* diverged when the *Salmonella enterica* ancestor acquired the SPI2 TTSS allowing invasion of deeper tissue. 3) *Salmonella enterica* subsp. I, II, IIIa, IIIb, IV, VI and VII acquired the ability to phase shift multiple flagellin subunits, thereby avoiding the immune response. 4) The subspecies continued to differentiate in their respective niches with subsp. I strains acquiring the ability to colonize warm-blooded host. Adapted from Baumler et al. (1998) and Porwollik et al. (2002).

intracellular pathogen associated with cold-blooded vertebrates. The next major event was the acquisition of the *Salmonella* pathogenicity island 2 (SPI2) type III secretion system that allows the organisms to survive in macrophages and, thus, colonize deeper tissue (see SPI2 TTSS). This event resulted in the split between the two currently recognized species, the presence of SPI2 being a defining characteristic of *S. enterica*. The seven subspecies of *S. enterica* (I, II, IIIa, IIIb, IV, VI and VII) continued to evolve to fit their respective niches. The ancestor of subsp. I, II, IIIb and VI acquired the ability to “phase shift” between multiple structural subunits of flagella, the primary organ of motility (see Flagella). This apparently provided *S. enterica* with a further ability to evade the immune systems of their hosts. The subsp. I ancestor then acquired the ability to colonize warm-blooded vertebrates, a major advance with striking implications for human health. The subsp. I strains have subsequently evolved to colonize a variety of hosts. Some serovars, such as Typhi, are host-specific, infecting only humans, whereas serovar Typhimurium is a generalist, capable of colonizing and causing disease in a range of mammalian species.

Chan et al. (2003) also analyzed subsp. I, IIIa and *S. bongori* strains using a serovar Typhimurium microarray. Although their results are in general agreement with those of Porwollik et al. (2002), important differences in interpretation exist between the two research groups. Indeed,

Chen et al. suggest that *S. enterica* subsp. IIIa (serovar *Arizonae*) is the most divergent of the *Salmonella*, with *S. bongori* being intermediate between subsp. IIIa and other *S. enterica* strains. Although the subsp. IIIa strains examined hybridized to some SPI2 gene probes, the pattern was heterogeneous. As described, *S. bongori* is apparently missing SPI2, which distinguishes it from *S. enterica* strains. Chan et al. raise the possibility that both *S. bongori* and *S. enterica* subsp. IIIa strains are derived from SPI2-containing ancestors but have lost some or all of these genes during their adaptation to their respective hosts.

Although the major island encoded virulence factors appear to delineate the evolution of the subspecies, they are certainly not the only genes specific to the various evolutionary branches. (See McClelland et al. [2001], Parkhill et al. [2001], Porwollik et al. [2002], Edwards et al. [2002], and Deng et al. [2003] for a more complete discussion of genes specific to *Salmonella* serovars.) Exchange of genetic material is taking place constantly. Whether or how much each of these subspecies-specific genes contributes to virulence or host range is an area of intense study. Alternatively, these genes could have simply been present in a particular strain at the moment it gained a major virulence factor that allowed it to take over the population. Throughout the evolution of *Salmonella*, certain strains acquired traits that made them significantly more fit or able to colonize a new niche, thus explaining the clonality of the various subspecies.

Some genes and traits are more highly variable than the bulk of the genome. This is particularly true for gene products that are subject to immunological selection, including fimbriae, O antigen, and flagella. Becoming increasingly clear is that many virulence factors are carried on bacteriophage that are lysogenized into the chromosome of particular strains (Thomson et al., 2004). For example, the Gifsy-2 phage encodes two major virulence factors, as well as other proteins that clearly interact with the host (Figueroa-Bossi and Bossi, 1999; Ho et al., 2002). Gifsy-2 lysogens are 100-fold more virulent in a mouse model of infection than an isogenic non-

lysogen (Ho et al., 2002). However, the presence of Gifsy-2 in different serovars of *Salmonella* is apparently unpredictable, being present in some isolates of certain serovars while absent in others (Fang et al., 1999; Ho and Schlauch, 2001). This observation is likely due to the fact that Gifsy-2 is a viable phage. Thus, “horizontal gene transfer” is constantly taking place. In other words, the presence or absence of the phage in a given isolate is not a reflection of the evolutionary history of the entire serovar.

Taxonomy

Salmonella nomenclature is undergoing constant change and can be confusing (Brenner et al., 2000; Euzéby, 2000). Until the mid-1900s *Salmonella* “species” were descriptive of the associated disease, e.g., *Salmonella typhi*, *Salmonella choleraesuis*, *Salmonella typhimurium*. Kauffmann (Kauffmann, 1941; Kauffmann, 1966; Kauffmann, 1971), extending the work of White (1926), established serological analysis of *Salmonella* (see Identification). Kauffmann argued that antigenic formula was “as good or even much better” than a species name (Kauffmann, 1971), thus serotype became equated with species. Newer isolates are named after the site of isolation, e.g., *Salmonella london*, *Salmonella paris* and *Salmonella casablanca*. Kauffmann, however, established “subgenera” based on biochemical characteristics. Contrary to his intention (Kauffmann, 1971), these subgenera also became equated with species, e.g., *Salmonella salamae* for subgenus II (Le Minor and Popoff, 1987). In 1966, the Ninth International Congress for Microbiology condensed the older names, for example, *Salmonella typhimurium*. There are currently over 2500 documented *Salmonella* serotypes (Popoff et al., 2001b).

Molecular studies suggested that all *Salmonella* are closely related (see Phylogeny), and Le Minor, Popoff, and colleagues (Le Minor, 1982; Le Minor, 1986) proposed the single species name *Salmonella choleraesuis* with seven recognized subspecies (Table 1). Subspecies I strains have recognized serovars, e.g., *Salmonella choleraesuis* subsp. *choleraesuis* serovar Typhi-

Table 1. *Salmonella* nomenclature.

Subspecies	Approved nomenclature	Widely accepted nomenclature
I	<i>Salmonella choleraesuis</i> subsp. <i>choleraesuis</i>	<i>Salmonella enterica</i> subsp. <i>enterica</i>
II	<i>Salmonella choleraesuis</i> subsp. <i>salamae</i>	<i>Salmonella enterica</i> subsp. <i>salamae</i>
IIIa	<i>Salmonella choleraesuis</i> subsp. <i>arizonae</i>	<i>Salmonella enterica</i> subsp. <i>arizonae</i>
IIIb	<i>Salmonella choleraesuis</i> subsp. <i>diarizonae</i>	<i>Salmonella enterica</i> subsp. <i>diarizonae</i>
IV	<i>Salmonella choleraesuis</i> subsp. <i>houstenae</i>	<i>Salmonella enterica</i> subsp. <i>houstenae</i>
VI	<i>Salmonella choleraesuis</i> subsp. <i>indica</i>	<i>Salmonella enterica</i> subsp. <i>indica</i>
V	<i>Salmonella choleraesuis</i> subsp. <i>bongori</i>	<i>Salmonella bongori</i>

murium or *Salmonella choleraesuis* subsp. *choleraesuis* serovar Typhi (note the use of italics and capitalization). These subspecies names currently have standing on the Approved Lists (Anonymous, 2003). The names *Salmonella arizonae*, *Salmonella bongori*, *Salmonella enteritidis*, *Salmonella typhi* and *Salmonella typhimurium* are also approved (see Genus *Salmonella* – Bacterial Nomenclature Up-to-Date).

Noting the potential confusion in using *Salmonella choleraesuis* to indicate organisms that cause very different diseases, e.g., serovar *Choleraesuis* versus serovar Typhi, Le Minor and Popoff (1987) proposed that the name *Salmonella enterica* be the sole species designation (Table 1) and that a particular stock of *Salmonella enterica* subsp. *enterica* (I) serovar Typhimurium strain LT2 be the type strain. The LT2 strain is Lilleengen strain type 2 (Lilleengen, 1948) and is extremely well characterized at the genetic, biochemical and molecular level. The proposal had received unanimous support from the Subcommittee on Enterobacteriaceae of the International Committee on Systematic Bacteriology at the Fourteenth International Congress of Microbiology (Penner, 1988). Subsequently, Reeves et al. (1989) proposed that *Salmonella bongori* be elevated to species status on the basis of molecular characterization. Although these proposals have never been officially sanctioned, this nomenclature is used widely and has been adopted by the Centers for Disease Control and Prevention (CDC), the American Society for Microbiology, and the WHO Collaborating Centre for Reference and Research on *Salmonella*, which is responsible for updating the Kauffmann-White Scheme (Popoff and Le Minor, 1997; Popoff et al., 2001b). Serovars of *Salmonella enterica* subsp. *enterica* are written in Roman letters (not italicized) and the first letter is capitalized. Serovars of other subspecies are designated by their antigenic formulae (see Identification). Since only *Salmonella enterica* subsp.

enterica strains are named, various shortened versions have become acceptable, such as *Salmonella enterica* serovar Typhimurium, *Salmonella* Typhimurium, or serovar Typhimurium. The *Salmonella* are also classified on the basis of serological differentiation of both O-antigen and flagellar antigens. This system and its nomenclature are described in Identification (see also Brenner et al., 2000).

Habitat

The *Salmonella* live primarily in the intestinal tracts of animals. *Salmonella enterica* subsp. *enterica* inhabit warm-blooded animals, whereas all other *S. enterica* subspecies and *S. bongori* are commensals of cold-blood animals and only rarely infect humans. The *S. enterica* subsp. *enterica* serovars can be further divided into those that are “host adapted” (primarily infecting one host but capable of causing disease in others), “host restricted” (known to infect only a single host), and “generalists” (capable of infecting a variety of animals, although the course of disease may differ in different hosts; Uzzau et al., 2000; Edwards et al., 2002; Table 2). Our understanding of the host range of *Salmonella* and the interaction of specific serovars with their host(s) is clearly affected by our preoccupation with human health; the nonhuman hosts listed in Table 2 are mostly food production animals or, in the case of rodents, responsible for contamination of food production facilities or involved in research. The real host range and distribution of *Salmonella* could be much larger.

Salmonella infection of many of these hosts often leads to a self-limiting gastroenteritis (see Disease and Gastroenteritis). However, to be maintained in its habitat, *Salmonella* must be able to persist or live commensally with at least some percentage of hosts and be efficiently transmitted from host to host. The molecular mecha-

	Choleraesuis	Swine	Humans
Host adapted	Dublin	Bovines	Human and ovines
	Typhimurium	Humans, poultry, swine, bovines, and rodents	None
Generalist	Enteritidis	Humans, poultry, and rodents	Swine and bovines

Adapted from Uzzau et al. (2000) and Edwards et al. (2002).

nisms of persistence are not well understood, and multiple systems are likely to contribute in the various serovars (Kingsley et al., 2003). Clearly, persistence and dissemination are genetically defined, as evidenced by the recent worldwide emergence of particular strains, such as serovar Typhimurium DT104 (Davis et al., 2002) and serovar Enteritidis PT4 (Guard-Petter, 2001).

Dissemination also requires that *Salmonella* survive outside of animals, and organisms can clearly be isolated from environmental sources. Contaminated water, for example, is a significant source of serovar Typhi in endemic areas (see Epidemiology). Infection of animals and food-stuffs is via contaminated feces. Clearly, *Salmonella* can replicate in contaminated food that is rich in nutrients and stored improperly. However, whether the bacteria are replicating or simply surviving in other environments is not clear. For example, because they filter large volumes of water to feed, mollusks can concentrate *Salmonella* that have contaminated coastal waters from sewage effluent and these contaminated shellfish can be a significant source for human infection (Noble, 1990). When oysters that were experimentally infected with serovar Typhi or serovar Typhimurium were placed in clean water, the number of bacteria associated with the shellfish was rapidly reduced, suggesting that the bacteria do not actually colonize and grow in the live shellfish (Hartland and Timoney, 1979; Nishio et al., 1981). Likewise, Gray and Fedorka-Cray (2001) have shown that serovar Choleraesuis survives for months and remains infective in swine feces. However, the number of recoverable cells consistently declined with time in these environments, suggesting that, although the organisms can survive, they do not replicate significantly.

Two cases where *Salmonella* has adapted to particular niches to maintain itself in the host population are particularly noteworthy. Serovar Typhi is a host-restricted human pathogen. Infection, particularly in children, results in an enteric fever (see Disease). Transmission is by the fecal-oral route. The bacteria invade the intestinal epithelium and invade macrophages. The bacteria replicate in macrophages and are disseminated throughout the body. Ninety percent of untreated Typhi patients who survive will completely clear the infection within several weeks. However, 10% will shed bacteria for up to 3 months, and 1–4% become long-term carriers, producing infective bacteria in their stools for over a year (Miller and Pegues, 2000; Parry et al., 2002). Bacteria replicating in the liver are shed through the gallbladder into the intestine and, thereby, the feces. Both acute (cholecystitis) and chronic infection of the gallbladder can develop. These chronic infections are more common in women and the elderly and are associated

with gallstones. It has been suggested that serovar Typhi can form biofilms on the gallstones, providing a more permanent habitat (Prouty et al., 2002a; see Genetics). Note that these carriers are asymptomatic, and many have no apparent history of typhoid fever but provide a constant source of infectious bacteria. The most famous carrier was “Typhoid Mary” (Leavitt, 1996).

Serovar Enteritidis is a generalist, capable of causing disease in a variety of hosts. Indeed, this serovar competes with serovar Typhimurium as the leading cause of human infections (see Epidemiology). In chickens, however, serovar Enteritidis causes an asymptomatic infection of the hen reproductive tract. This leads to vertical transmission, where the bacteria contaminate the egg prior to the deposition of the shell (Guard-Petter, 2001). Thus, these otherwise healthy hens provide a long-term source of *Salmonella*.

Isolation

The isolation of *Salmonella* spp. from food products utilizes a selective enrichment method (Harrigan, 1998). Samples, after resuscitation in, for example, peptone water, are used to inoculate selenite cystine broth or Rappaport-Vassiliadis medium, both which enrich for *Salmonella* and *Shigella*. Selenite cystine broth is commonly used for enrichment of *Salmonella* because selenite inhibits growth of most coliforms but has only mild effects on *Salmonella*. The resulting cultures are then plated on selective and differential media such as brilliant green phenol red agar or bismuth sulfite agar. Once putative single colonies of *Salmonella* have been isolated, biochemical and serological methods can be used to definitively determine whether the samples indeed contain *Salmonella* (see Identification).

The isolation of *Salmonella* from clinical samples, such as stool samples, involves the use of a nonselective medium such as blood agar, or selective and differential media such as MacConkey or a highly selective medium such as bismuth sulfite agar (Farmer, 1999). Bismuth sulfite agar is particularly useful in identifying *Salmonella* because bismuth, a heavy metal, inhibits the growth of many other microorganisms (Farmer, 1999). On bismuth sulfite agar, most *Salmonella* (Table 3) appear black because of the production of hydrogen sulfide, which reacts with ferrous sulfate to form the black precipitate. The sensitivity of culturing stool for *Salmonella* is estimated to be 70% (Voetsch et al., 2004).

Recently a great deal of interest has focused on the presence of nonculturable but viable *Salmonella* species in clinical, environmental, and food samples. Recent studies suggest that the addition of certain supplements increases

the recovery of stressed but otherwise nonculturable cells. These supplements include 1) the siderophore ferrioxamine E, 2) the commercially available antioxidant “Oxyrase,” and 3) heat stable enterobacterial “autoinducer” (Reissbrodt et al., 2002).

Identification

Proper identification of *Salmonella* requires isolation, biochemical characterization, and serotyping. The *Salmonella* are members of the Enterobacteriaceae: Gram-negative, oxidase-negative, rod-shaped bacteria ($1 \times 2 \mu\text{m}$). Most *Salmonella* strains are motile and ferment glucose with the production of acid and gas. Table 3 lists some useful biochemical tests to distinguish *Salmonella* from other enterics and to differentiate *Salmonella* subspecies. Many of these tests are most easily carried out using commercially available systems, such as API-20E (bioMérieux, Inc.) or BBL Enterotube II (BD; see O'Hara et al. [2003] for more information).

Salmonella are serotyped on the basis of the antigenic structure of the O antigen (heat stable somatic antigen; see Structure), the H antigen (heat labile; flagellin; see Structure)), and the Vi antigen (capsule; see Structure), if present. Serotyping is only valid on strains that are biochemically confirmed as *Salmonella* because the antisera are crossreactive with other bacteria. The serotypes are designated according to the Kauffmann-White scheme (Popoff, 2001a). Note that the CDC used a “Modified Kauffmann-White Scheme” before January 2003 but now uses the standard scheme.

O Antigen

Lipopolysaccharide (LPS) forms the outermost layer of Gram-negative bacteria and serves to protect the cell from the environment. LPS is composed of three portions: lipid A, core oligosaccharide, and a polymer of O-antigen subunits (Raetz and Whitfield, 2002). In pathogenic bacteria, LPS plays an important role in the interaction between the bacterium and its host, having dramatic effects on the immune system. Whereas the lipid A moiety is the predominant cause of the endotoxic effects of LPS, the O antigen is the most immunodominant portion of the molecule.

Because of selection due to the immune system of *Salmonella* hosts (Kingsley and Baumler, 2000), bacteriophages (which often use O-antigen as a receptor), and protozoal predation (Wildschutte et al., 2004), the structure of the O-antigen is very variable among strains of *Salmo-*

nella. Structurally, the O antigens can differ in monosaccharide components, linkages between monosaccharides, and other minor modifications, such as acetylation. Even subtle chemical changes in O-antigen structure have profound effects on antibody recognition (Kim and Slauch, 1999). Thus, the Kauffmann-White scheme recognizes O-antigen factors 1–67 (not inclusive) and divides the *Salmonella* into approximately 50 different serogroups (Table 4). As examples, the basic structure of the O-antigen subunits for groups B and D1 and common modifications are shown in Fig. 2.

The enzymes required for synthesis of the O-antigen specific monosaccharides and assembly of the subunit are located in the O-antigen gene cluster at approximately centisome 45 on the serovar Typhimurium strain LT2 chromosome (McClelland et al., 2001). Not surprisingly, comparison of the gene cluster among different serovars of *Salmonella* shows considerable variation (Wang et al., 2002). Genes encoding the synthesis of more common monosaccharides (e.g., galactose) are located elsewhere in the chromosome, while many of the enzymes that modify the O antigen are carried on viable or cryptic prophages (Slauch et al., 1996). The presence or absence of these modifications is often variable within a serogroup.

Table 4 lists the O factors that comprise the different O-antigen groups. The majority of human isolates are in serogroups A–E4. However, serogroup and subspecies are not strictly correlated (see Taxonomy), i.e., subspecies I strains are found in all serogroups. Strains are initially tested against antisera for Groups A–E4. Positive results are confirmed using the appropriate antisera against the single factors that will distinguish between groups. If agglutinations with Groups A–E4 antisera are negative, other Group antisera are tested, usually in pools, e.g., antisera against Groups 51–55. (In-depth technical information about O-antigen serogrouping is found in Brenner and McWhorter-Murlin [1998] and Difco [1998].)

If no agglutination occurs with all group antisera, then possibly the strain (e.g., serovar Typhi) is producing Vi capsule that is blocking antibody access to the O antigen (see Vi Antigen). Previous biochemical analysis should suggest serovar Typhi strains. Alternatively, the strain could be “rough” and is not making O antigen. These strains will either not agglutinate or give weak cross-agglutination in a variety of antisera. The negative strain could be “mucoid” and produce a capsule other than Vi. Both rough and mucoid strains can be streaked out and typical colonies can be identified and tested. Finally, the strain might not be *Salmonella*. Biochemical tests should be confirmed.

H Antigens

Most *Salmonella* strains are motile, producing peritrichous flagella. The flagella are exposed on the surface of the bacteria and are highly immunogenic. Therefore, as in the case of O antigen,

Structure	O-antigen
$\begin{array}{c} \alpha\text{-D-Abe} \\ \downarrow \begin{smallmatrix} 1 \\ 3 \end{smallmatrix} \\ \rightarrow 2\text{-}\alpha\text{-D-Man}\text{-(1}\rightarrow 4\text{)-}\alpha\text{-L-Rha}\text{-(1}\rightarrow 3\text{)-}\alpha\text{-D-Gal}\text{-(1}\rightarrow \end{array}$	O4, O12
$\begin{array}{c} \alpha\text{-D-Abe-2-O-Acetyl} \\ \downarrow \begin{smallmatrix} 1 \\ 3 \end{smallmatrix} \\ \rightarrow 2\text{-}\alpha\text{-D-Man}\text{-(1}\rightarrow 4\text{)-}\alpha\text{-L-Rha}\text{-(1}\rightarrow 3\text{)-}\alpha\text{-D-Gal}\text{-(1}\rightarrow \end{array}$	O4, O5, O12
$\begin{array}{cc} \alpha\text{-D-Abe} & \alpha\text{-D-Glu} \\ \downarrow \begin{smallmatrix} 1 \\ 3 \end{smallmatrix} & \downarrow \begin{smallmatrix} 1 \\ 4 \end{smallmatrix} \\ \rightarrow 2\text{-}\alpha\text{-D-Man}\text{-(1}\rightarrow 4\text{)-}\alpha\text{-L-Rha}\text{-(1}\rightarrow 3\text{)-}\alpha\text{-D-Gal}\text{-(1}\rightarrow \end{array}$	O1, O4, O12

$\begin{array}{c} \alpha\text{-D-Tyv} \\ \downarrow \begin{smallmatrix} 1 \\ 3 \end{smallmatrix} \\ \rightarrow 2\text{-}\alpha\text{-D-Man}\text{-(1}\rightarrow 4\text{)-}\alpha\text{-L-Rha}\text{-(1}\rightarrow 3\text{)-}\alpha\text{-D-Gal}\text{-(1}\rightarrow \end{array}$	O9, O12

Fig. 2. Structures of representative O antigens. The basic structure (e.g., O4 and O12) can be modified. The O5 antigen is the result of acetylation of the 2-hydroxyl group on abequose, encoded on a cryptic bacteriophage (Slauch et al., 1996). The O1 antigen is a phage-mediated addition of glucose on the galactose. The O27 epitope results from altered linkage between the O-antigen subunits (Wang et al., 2002). The difference between O4 and O9 is the use of abequose versus tyvelose attached to the mannose residue. Adapted from D. Liu et al. (1995) and Wang et al. (2002).

there has been selection for considerable variation in the surface-exposed domains of the flagellar subunit. Indeed, subsp. I, II, IIIa and VI are biphasic, capable of producing two (and sometimes three) functionally equivalent but immunologically distinct flagellar subunits (see both Phylogeny and Flagella). Serological distinction among the H antigens constitutes the second part of the Kauffmann-White scheme.

Phase 1 H antigens are designated by lower-case letters, “a” through “z” and then “z1,” “z2,” “z3,” etc. Phase 2 antigens are designated by numerals, “1,” “2,” “3,” etc. However, some strains produce Phase 1 antigens in Phase 2. H antigens are identified only after the O-antigen group has been determined; particular H antigens are associated with certain serogroups. H antigens are usually determined using a tube agglutination assay. Initially, agglutination with mixed unabsorbed H antisera is performed. These pools are designed to be used with certain O-antigen groups as they represent the most common H antigens associated with these groups. Further identification requires the use of absorbed single H antisera. (In depth technical information about H-antigen serotyping is found in Brenner and McWhorter-Murlin [1998] and Difco [1998].) The Spicer-Edwards H antisera

are combined sera designed to easily distinguish the most common Phase 1 antigens (Difco, 1998).

Within the culture of most strains, both Phase 1 and 2 H antigens will be expressed. However, fresh single colony isolates may only express one phase. To determine the other phase, one can perform a “phase reversal.” This is accomplished by inoculating the strain of interest into motility agar that contains H antiserum that is known to agglutinate. The antibodies in the serum will immobilize cells expressing the original H-antigen (at any given time, one antigen being expressed) but not cells that have undergone a phase transition and so are expressing a new antigen. The progeny of the latter will swim away from the site of inoculation. These cells can be isolated and the new H antigen determined. If the strain does not give rise to motile cells in the presence of the H antiserum, it could be monophasic.

Vi Antigen

The Vi antigen is a capsular polysaccharide produced by serovar Typhi and Paratyphi C strains, some *Citrobacter* strains, and occasionally by strains of serovar Dublin. The capsule is a linear homopolymer of α -1,4 2-deoxy-2-*N*-acetylgalactosamine uronic acid which can be O-acetylated at the C-3 position (Daniels et al., 1989). The enzymes required for synthesis and export of the capsule are encoded in what is historically called the “*viaB* locus,” which is composed of at least 10 genes (*tvIA-E* and *vexA-E*) at 93.9 centisomes on the chromosome (Virlogeux et al., 1995). Transcription of these genes is under the control of the *viaA* locus, which is now known to encode the two-component regulatory system RcsB and RcsC (Virlogeux et al., 1996).

The presence of the Vi capsule is determined by slide agglutination. If, on the basis of biochemical analysis, a strain is suspected to be serovar Typhi or Paratyphi C, then agglutination with Vi antisera is performed along with testing with the appropriate O group antisera. Note that the presence of the capsule can block antibody recognition of the O-antigen. Therefore, if a strain is positive for Vi antigen, the strain should be heated in boiling water for 15 min, cooled, and tested again. Upon heating, a serovar Typhi strain should be negative for Vi antigen and positive for O group D (see Difco, 1998).

Nomenclature for Reporting Serotype

When designating the serotypes of *Salmonella* strains, the O antigen is given first, followed by the Vi (if present), and the H antigen(s), Phase 1 and then Phase 2. The major antigens are

separated by colons and the individual antigens by commas. For example, serovar Typhimurium is designated *Salmonella* 1, 4, [5], 12:i:1, 2. Note that antigens that result from phage lysogeny are underlined. Antigens in brackets are also variable, although not known to be mediated by viable phage. See Table 5 for further examples.

Phage Typing and Other Methods of Subserotype Classification

Salmonella strains within a given serotype can be further differentiated using both classical and molecular techniques. Phage typing is one of the oldest methods for classification of *Salmonella* serotypes. Phage-typing systems exist for serotypes Typhi (Craigie and Yen, 1938), Typhimurium (Anderson, 1964; Anderson et al., 1977), Enteritidis (Ward et al., 1987), Dublin, Paratyphi A and Paratyphi B (Felix and Callow, 1943; Anderson, 1964), as well as other serotypes. These systems are based on the ability to plaque a defined set of phage, each of which has been propagated on a particular strain. Differential plaquing of the phage is dependent on a combination of factors (Schmieger, 1999). First is the presence of the appropriate phage receptor. Note that these are subtle differences between strains within a serotype and are likely due to modifications of the receptor by resident lysogenic phage. The Typhimurium typing phage, for example, generally use O-antigen as receptor (see O-antigen) and the Typhi phage use Vi antigen (see Vi antigen). Differences in phage sensitivity are subtler than can be detected using typing sera. Second are differences in host restriction-modification systems. Third are the presence of lysogenic phage or cryptic phage that can confer either immunity or superinfection exclusion systems. Note that there can also be recombination between the typing phage and resident phage yielding phage with new properties. The typing phage can also cause induction of resident phage (Schmieger, 1999). Because of the subtleties involved and the fact that the typing phage must be propagated precisely, if at all, phage typing is best done by particular reference laboratories.

Phage typing is a powerful and sensitive tool for epidemiology. For example, the emergence of particular strains such as serotype Typhimurium phage type DT104 can be monitored throughout the world (Cloeckaert and Schwarz, 2001). Other techniques for subserotype classification include differentiating biochemical characteristics (bio-type), MLEE, or other molecular techniques (such as plasmid profiling, AFLP, or “variable number of tandem repeats”-based fingerprinting [VNTR]; Selander et al., 1996; Lindstedt et al., 2003; Soll et al., 2003). Indeed, VNTR apparently

Table 5. Serotypes for the most common *Salmonella* isolates (all subspecies I).

detects subsets of phage type DT104 (Lindstedt et al., 2003).

Preservation

Clinical or environmental samples should be used as soon as possible for isolation of *Salmonella* (Harrigan, 1998; Farmer, 1999). If this is not possible, food or environmental samples can be refrigerated (Harrigan, 1998); transport media is available for stool samples (Farmer, 1999). Pure stocks can be stored using several methods (Miller, 1992) including “stabs” in which a single colony is stabbed several times into sterile solid medium in a vial using a sterile loop. The vials are tightly sealed and maintained at room temperature. Although a time-honored tradition, this method is not recommended for long-term storage; the bacteria must continue to grow in the medium to maintain viability and evolution

is taking place (Edwards et al., 2001). More permanent storage is achieved by either lyophilization or freezing at -70°C in $\geq 10\%$ glycerol or 10% DMSO. Stocks will last decades under these conditions.

Physiology

The *Salmonella*, in the family Enterobacteriaceae, are facultatively anaerobic Gram-negative, rod-shaped bacteria. Given the close relationship with *E. coli* and the many years devoted to its study, the overall metabolism of *Salmonella* is well understood. The cells are typically $0.7\text{--}1.5\ \mu\text{m}$ by $2\text{--}5\ \mu\text{m}$. They will grow at $7\text{--}48^{\circ}\text{C}$ with an optimum growth at 37°C (mesophile) and at pH 4.05–9.5 with an optimal growth at pH 6.5–7.5 (neutrophile). *Salmonella* grows optimally at a water activity of 0.995 (Cox, 1999).

Salmonella are chemoorganotrophs. They have both fermentative and oxidative metabolism. The primary route for metabolism of carbohydrates is the Embden-Meyerhof pathway (glycolysis). They ferment glucose to formate (with the production of gas), and to ethanol, acetate, or lactate. The electron transport chain is cytochrome-based with oxygen, nitrate, fumarate, dimethyl sulfoxide, and trimethylamine N-oxide (TMAO) as terminal electron acceptors. Enterics do not have a cytochrome *c* or cytochrome *c* oxidase in the transport chain and are classified, therefore, as “oxidase minus.” A more complete list of metabolic properties is given in Table 3. The specific metabolic characteristics that distinguish these organisms from other enterics are that *Salmonella* usually cannot metabolize lactose or sucrose, can hydrolyze 4-methylumbelliferyl caprylate (MUCAP), and produce hydrogen sulfide. Indeed, the genes for production of hydrogen sulfide can be used as *Salmonella*-specific molecular markers (Porwollik et al., 2002). Most serotypes of *Salmonella* are prototrophs; the exceptions are some of the host-adapted serotypes (Table 2). For examples, serotype Typhi strains are often cysteine and tryptophan auxotrophs, while serovar Pullorum strains require methionine, cysteine, thiamine and nicotinamide (at high temperature; K. Karberg, personal communication).

Genetics

Genetic analysis in serovar Typhimurium is a high art form, and *Salmonella* rivals *E. coli* as far as our understanding of bacterial cell structure, biology and physiology is concerned (see <http://www.ecosal.org> {www.ecosal.org}). Classic genetic tools, such as bacteriophage P22-mediated transduction (Maloy et al., 1996), combined with more modern techniques, such as Lambda Red-mediated recombination (Datsenko and Wanner, 2000; Ellermeier et al., 2002), provide the means to manipulate, at will, *Salmonella* strains for the study of any biological problem of interest.

The complete genome sequences of serovar Typhimurium strain LT2 (McClelland et al., 2001) and serovar Typhi strains Ty2 (Deng et al., 2003) and CT18 (Parkhill et al., 2001) are known (see {www.ncbi.nlm.nih.gov}). Representatives of additional *Salmonella* serovars are also being sequenced (see <http://www.salmonella.org> {[salmonella.org](http://www.salmonella.org)}). The LT2 genome is approximately 4857 kilobases with 4489 putative protein coding sequences. The DNA is 53 mol% G+C. In addition, the virulence plasmid, pSLT, is approximately 94 kilobases with 108 putative protein

coding regions. The pSLT plasmid is self transmissible (Ahmer et al., 1999a) and is indicative of virulence plasmids carried by most nontyphoid subsp. *enterica* strains (Guiney et al., 1995). The two serovar Typhi genomes are also approximately 4800 kilobases with approximately 4600 putative protein coding sequences. These two genomes are 98% identical. Although there is an obvious synteny in overall genomic organization, the two Typhi genomes differ from each other and from the LT2 genome by virtue of inversions between rRNA operons. Indeed, the host-restricted serovars are known to be prone to these chromosomal rearrangements for reasons that are unknown (Helm et al., 2003). The other striking difference is the large number (~200) of pseudogenes found in the Typhi strains. The loss of these genes presumably reflects the restricted host range, but there is no direct proof of this hypothesis. As has been found with virtually all bacterial genomic sequences, a significant number of genes are not found in the close relatives. For example, 29% of the LT2 genes are not found in *E. coli* K12 and 11% are not present in the Typhi genomes. These horizontally transferred genes are found throughout the chromosome on islands ranging from single genes to sets of genes (>50 kilobases). In several cases, these larger clusters are viable or cryptic phage genomes (see also Thomson et al., 2004).

What makes *Salmonella* unique from *E. coli* K12, of course, is pathogenesis. *Salmonella* serovars are capable of infecting a variety of different hosts and causing diseases ranging from a mild self-limiting gastroenteritis to a potentially lethal systemic infection (see Disease). Serovar Typhimurium normally causes a self-limiting gastroenteritis in humans but in a mouse is capable of causing a systemic infection that resembles human Typhoid fever caused by serovar Typhi. The mouse infection model and the sophisticated genetic techniques available for serovar Typhimurium have led to an extensive knowledge of host-pathogen interaction. Here, the focus is on the genetics of virulence in serovar Typhimurium in the mouse model. A brief overview of the infection cycle is provided, and the genes and gene products important at each stage are discussed. Reviews of particular aspects of *Salmonella* pathogenesis are referenced throughout.

Overview of the *Salmonella* Infectious Cycle in Mice

Salmonella infection normally occurs via the ingestion of contaminated water or food products. *Salmonella* must survive numerous host

environments and defenses to produce a productive infection. The first of these barriers is the acidic condition encountered in the stomach. After passing through the stomach *Salmonella* colonizes the small intestine where it preferentially targets and invades the most distal Peyer's patch of the small intestine (Carter and Collins, 1974). Serovar Typhimurium can gain access to the underlying lymph tissue via M cells (phagocytic epithelial cells) and villous (nonphagocytic) epithelial cells of the small intestine using the *Salmonella* pathogenicity island 1 (SPI1) type three secretion system (TTSS). After gaining access to the underlying lymph tissue, serovar Typhimurium continues to replicate within the Peyer's patch tissue. Eventually serovar Typhimurium is disseminated to the target organs of the liver, spleen and bone marrow where the bacteria continue to replicate within macrophages eventually leading to septicemia and death of the host. Thus, *Salmonella* are facultative intracellular pathogens. Replication within macrophages requires a second TTSS, encoded on *Salmonella* pathogenicity island 2 (SPI2). As the number of organisms continues to increase, *Salmonella* can infect essentially all tissues of the body. Eventually, the host dies as a result of complications from septic shock and organ failure. During the infection *Salmonella* can be reintroduced into the small intestine via the gallbladder and disseminated into the environment. The ability of serovar Typhimurium to survive the various conditions and host defenses encountered during an infection requires a number of virulence factors, as well as the appropriate regulation of these virulence factors.

Acid Tolerance Response

Infection by *Salmonella* is by the oral route as a result of ingesting contaminated food, water, or dairy products (Miller and Pegues, 2000). To produce a productive infection, *Salmonella* species must first survive the acidic conditions encountered in the stomach (Foster and Hall, 1990). Serovar Typhimurium can survive extremely low pH after growth in mildly acidic conditions (pH 4–5), a process termed “the acid tolerance response” (“ATR”; Audia et al., 2001). Serovar Typhimurium contains two distinct systems, the log phase ATR and stationary phase ATR. The log phase ATR induces expression of more than 50 proteins termed “acid shock proteins” (Hall and Foster, 1996). Several regulatory genes are required for the log phase ATR including *rpoS* (an alternative σ factor required for stationary phase gene expression), Fur (an iron sensing regulator of iron metabolism), and PhoPQ (a two-component regulatory system involved in regulation of other virulence genes; Lee et al.,

1995; Hall and Foster, 1996; Bearson et al., 1998; see PhoPQ). The second ATR system in serovar Typhimurium is an acid-induced RpoS-independent stationary phase ATR regulated by OmpR/EnvZ; Bang et al., 2000; Bang et al., 2002).

Attachment and Colonization of the Small Intestine

Organisms that survive the gastric barrier colonize the small intestine. Numerous studies have shown that serovar Typhimurium preferentially attaches to and invades the most distal Peyer's patch of the small intestine (Carter and Collins, 1974; Jones et al., 1994; Wallis and Galyov, 2000). The apparent tropism of serovar Typhimurium for the M cells of the Peyer's patch as compared to the villous epithelial cells has led to the hypothesis that fimbriae mediate attachment of the bacteria to the M-cell surface. On the basis of the completed genome sequence, serovar Typhimurium potentially encodes 13 fimbrial operons (*agf* (*csg*), *fim*, *pef*, *lpf*, *bcf*, *saf*, *stb*, *stc*, *std*, *stf*, *sth*, *sti* and *stj*; McClelland et al., 2001; Townsend et al., 2001; Edwards et al., 2002; Humphries et al., 2003). Production of 11 of these fimbriae has been detected, with expression being dependent on growth conditions (Humphries et al., 2003). Only a few of these fimbriae have been studied in any detail (reviewed in Humphries et al., 2001).

Serovar Typhimurium, like most Enterobacteriaceae, produces a type-1 fimbriae encoded by *fimAICDHF* that characteristically binds to mannose residues of host cells. A mutation in *fimA* significantly decreased the binding of serovar Typhimurium to mouse enterocytes (Thankavel et al., 1999). However, a *fim* mutation has only a minor effect on virulence in serovar Typhimurium (Lockman and Curtiss, 1992). Serovar Typhimurium SL1344 strains containing mutations in *fim* are unable to attach to or invade human epithelial cells in vitro but remain unaffected for invasion of cell lines from other host species. This suggests that the serovar Typhimurium type 1 fimbriae may mediate attachment to different hosts (Baumler et al., 1997a). Recent evidence suggests that there is a great deal of allelic variation within *fimH*, which encodes the adhesin (Boddicker et al., 2002).

Serovar Typhimurium also encodes fimbriae called “long polar fimbriae” (“Lpf”; Baumler and Heffron, 1995). The Lpf fimbriae mediate attachment of serovar Typhimurium to the M-cells of the Peyer's patch but not to villous epithelial cells of the small intestine (Baumler et al., 1996b). Mutations that disrupt Lpf increase the oral LD₅₀ in mice ca. fivefold and delay death compared to the wildtype by about 3 days

(Baumler et al., 1996b). The virulence plasmid of serovar Typhimurium, pSLT, contains a fimbrial operon termed “the plasmid-encoded fimbriae (*pef*) operon.” Mutations in the *pef* genes have been reported to decrease the ability of serovar Typhimurium to attach to the murine small intestine (Baumler et al., 1996a). Mutations in *pef* also increase the oral LD₅₀ ca. 2.5-fold (Baumler et al., 1996a).

Serovar Typhimurium contains a fourth fimbrial operon termed the “*agf* operon,” which produces thin aggregative fimbriae that are analogous to the curli fimbriae of *E. coli*. The Agf protein promotes bacterial autoaggregation and has been implicated in both biofilm formation and virulence (Romling et al., 2000). Mutations in *ompR* block transcription of the *agf* genes suggesting that OmpR is either directly or indirectly required for transcription of *agf* (Romling et al., 1998).

Recent evidence suggests that these operons may be functionally redundant. van der Velden determined that an *lpf pef* and *fim* triple mutant did not significantly decrease virulence, whereas a triple mutant of *lpf pef* and *agf* increased the oral LD₅₀ ca. 30-fold, and the quadruple mutant, *lpf pef agf* and *fim*, showed a similar increase in the oral LD₅₀ (Van der Velden et al., 1998). This strongly suggests that Lpf, Pef and Agf fimbriae are functionally able to compensate for one another in the BALB/c mouse model of infection (Van der Velden et al., 1998). Whether colonization of other hosts requires a different repertoire of fimbrial operons remains unclear, although the presence of such a large number of fimbrial operons suggests this may be the case. The contribution of the remaining nine fimbrial operons to virulence remains to be tested.

Invasion of Epithelial Cells

A critical step in the infection process of *Salmonella* species is the ability to invade the intestinal epithelial barrier (Darwin and Miller, 1999b). Serovar Typhimurium may be capable of breaching the epithelium in more than one way. Serovar Typhimurium invades normally nonphagocytic intestinal epithelial cells using a type three secretion system (TTSS) encoded by *Salmonella* pathogenicity island 1 (SPI1; Darwin and Miller, 1999b; Galan, 1999; Lostroh and Lee, 2001b). The SPI1 TTSS forms a needle-like structure capable of injecting so-called “effector proteins” directly into the cytosol of host cells (Kubori et al., 1998; Kubori et al., 2000; Kimbrough and Miller, 2000; Kimbrough and Miller, 2002). SPI1 effectors cause a rearrangement of the eukaryotic cell cytoskeleton, facilitating bacterial engulfment and invasion of the intestinal epithelium. Injection of these proteins also induces a

series of proinflammatory cytokines that trigger mucosal inflammation and infiltration of neutrophils (Wallis and Galyov, 2000). This inflammatory response is thought to contribute to gastroenteritis symptoms associated with *Salmonella* infection (Wallis and Galyov, 2000; see Gastroenteritis).

The SPI1 locus comprises approximately 35 genes that encode components of secretion apparatus, several effector proteins, transcriptional regulators of genes encoded both within SPI1 and elsewhere in the chromosome, and chaperones required for assembly of the apparatus or secretion of effectors (Lostroh and Lee, 2001b).

The SPI1 TTSS Apparatus

Approximately 17 proteins, homologs of which are found in essentially all type III systems (Hueck, 1998), comprise the secretion apparatus and form a “needle complex” that has a cytoplasmic “export apparatus,” inner membrane components, outer membrane components, and the needle, which extends out from the cell (Kimbrough and Miller, 2002). Presumably, target proteins are secreted directly from the cytoplasm through this needle. Exported proteins include SipB, SipC and SipD, which are proposed to act as a “translocon” that integrates into the eukaryotic cell membrane as a prerequisite for delivery of other effector proteins (Darwin and Miller, 1999b; Lostroh and Lee, 2001b). Interaction of the needle with the translocon is assumed to complete the apparatus and allow direct injection of effector proteins.

SPI1 Effector Proteins

The most striking result of SPI1 TTSS action is an actin cytoskeletal rearrangement that leads to bacterial engulfment and invasion. The SPI1 TTSS injects a number of effector proteins responsible for this and other physiological responses. These include the SPI1 encoded effectors SipA (SspA), AvrA, and SptP; the SPI1 encoded translocon proteins SipB, SipC and SipD (which apparently also have effector function); and effectors that are encoded on pathogenicity islands or bacteriophage elsewhere in the chromosome, SopA, SopB (SigD), SopD, SopE1, SopE2, SspH1 and SlrP. The biochemical functions of the various effectors and their roles in *Salmonella* pathogenesis are just beginning to be understood.

Individual mutations in *sopE1*, *sopE2* or *sopB* result in only minor invasion defects, whereas a strain containing mutations in all three genes has a severe invasion defect (Zhou and Galan, 2001a), suggesting that these effectors are functionally redundant. The *sopE1* and *sopE2* genes,

encoded by the SopE phage and within a *Salmonella* specific region near *proQ*, respectively, are paralogs that promote actin rearrangement by acting as GDP/GTP exchange factors for two members of the Rho family of GTPases, Rac1 and Cdc42 (Bakshi et al., 2000; Friebe and Hardt, 2000; Stender et al., 2000; Friebe et al., 2001). The activation of Rac1 and Cdc42 promotes large-scale actin rearrangement resulting in the characteristic membrane ruffling and engulfment of the bacteria (Zhou et al., 2001b), as well as triggering a signal transduction cascade that leads to the activation of NF- κ B (Hobbie et al., 1997). SopB acts as an inositol phosphatase and produces a molecule that acts as an indirect activator of Cdc42 (Norris et al., 1998).

SipA and SipC are actin-binding proteins that promote bacterial mediated endocytosis. The binding of SipA to actin is believed to decrease the critical concentration required for actin polymerization by inhibiting actin depolymerization and binding of T-plastin (Zhou et al., 1999a; Zhou et al., 1999b; Higashide et al., 2002). SipC is a two-domain protein that can act to nucleate and bundle actin (Hayward and Koronakis, 1999). The N-terminal portion of SipC binds F-actin, and the C-terminus is required for actin nucleation (Hayward and Koronakis, 1999). The relevance of these activities in vivo has yet to be determined because a *sipC* mutation completely blocks translocation of all the effectors, as it is a member of the translocon (Collazo and Galan, 1997).

SptP is a GTPase-activating protein for both CDC42 and Rac1 that promotes actin depolymerization, opposing the activating functions of SopE, SopE2 and SopB (Fu and Galan, 1999). During invasion, serovar Typhimurium causes large-scale actin rearrangement. After internalization of serovar Typhimurium, the cells are able to return to a normal cellular architecture (Galan and Zhou, 2000). SptP has been suggested to play a role in this recovery because of its GTPase activating protein (GAP) activity (Galan and Zhou, 2000). SspH1 (Haraga and Miller, 2003) and AvrA (Collier-Hyams et al., 2002) also attenuate the role of other effectors by downregulating NF- κ B activation. A null mutant of *sptP* decreases invasion ca. twofold (Darwin and Miller, 1999b). Loss of SspH1 alone does not confer a significant defect in a calf model (Miao et al., 1999), nor does loss of AvrA confer an obvious phenotype (Hardt and Galan, 1997; Zhang et al., 2002).

SipB, also a member of the translocon, has been shown to interact with caspase-1 to induce necrosis in macrophages (see Peyer's Patch Survival). The biochemical activities of SlrP, SopA and SopD are unknown. Phenotypically, mutations in *sopA* or *sopD* (as well as *sipA*, *sopB* and

sopE2) significantly reduce fluid accumulation in a calf model of *Salmonella*-induced diarrhea (Zhang et al., 2002). Mutants lacking SlrP are attenuated in a mouse model after oral infection but are fully virulent in the calf model (Tsolis et al., 1999).

SPI1 TTSS Chaperones

Chaperones are often required for the secretion and translocation of effector proteins in TTSS. Serovar Typhimurium contains three known SPI1 related chaperones: InvB acts as chaperone for SipA (Bronstein et al., 2000), SopA (Ehrbar et al., 2004), SopE1 (Lee and Galan, 2003) and SopE2 (Ehrbar et al., 2003); SicA acts on SipB and SipC (Tucker and Galan, 2000); and SicP is the chaperone of SptP (Stebbins and Galan, 2001; Lee and Galan, 2004). The presence of SicP and InvB increases stability of their respective effectors SptP and SipA without affecting the transcriptional expression of either *sptP* or *sipA* (Bronstein et al., 2000; Stebbins and Galan, 2001). The case of SicA is more complicated as mutants of *sicA* decrease expression of the *sic/sip* operon at the transcriptional level (Tucker and Galan, 2000; see SPI1 Encoded Regulators). InvE also seems to play a role in secretion by interacting with a chaperone-effector complex (Kubori and Galan, 2002).

SPI1 Encoded Regulators of the SPI1 TTSS

The expression of the SPI1 TTSS is controlled in response to a specific combination of environmental signals that presumably act as a cue that the bacteria are in the appropriate anatomic location (Bajaj et al., 1996; Schechter et al., 1999; Slauch, 2000). In the laboratory, the system is active when cells are grown under "SPI1 inducing conditions"-high osmolarity and low oxygen. Regulation is mediated primarily via control of the level of HilA, a member of the OmpR/ToxT family of transcriptional regulators encoded on SPI1 (Lee et al., 1992; Bajaj et al., 1995; Lostroh and Lee, 2001a). HilA directly activates expression of the *prg/org* and *inv/spa* operons in SPI1 by binding just upstream of the -35 sequences of P_{prgH} and P_{invF} (Lostroh and Lee, 2001a). Activation of P_{invF} increases production of InvF, a member of the AraC family of transcriptional regulators (Kaniga et al., 1994). InvF then induces expression of effector proteins encoded both within and outside of SPI1, including *sicA* (SPI1), *sopE* (SopE phage in strain SL1344) and *sopB* (SPI5; Lostroh and Lee, 2001a).

Activation of promoters by InvF requires SicA, a TTSS chaperone (Darwin and Miller, 1999a; Eichelberg and Galan, 1999a; Darwin and Miller, 2000), which has been suggested to stabi-

lize a complex between InvF, RNA polymerase, and DNA (Darwin and Miller, 2001). This raises the intriguing possibility that once the secretion apparatus is assembled, the effector proteins are secreted, resulting in free SicA. The free SicA can then form a complex with InvF to activate expression of numerous effector proteins. This constitutes a negative feedback loop that couples expression of effector proteins to assembly of the TTSS, analogous to the FliA/FlgM controlled expression of the class three flagellar genes (Chilcott and Hughes, 2000). As of yet there is no proof of this model, but it remains an attractive hypothesis.

Another gene located on SPI1, *sprB*, appears to lie in an operon with *hilC* and has been hypothesized to be a regulator because the predicted protein sequence contains a LuxR-like helix-turn-helix motif (Eichelberg et al., 1999b). To date neither overexpression of *sprB* nor *sprB* null mutations affect expression of any of the SPI1 encoded genes tested (Eichelberg et al., 1999b). Still unknown is whether SprB regulates genes located outside of SPI1, or SprB can regulate the expression of invasion genes under different conditions than those tested.

Direct Regulators of *hilA*

Expression of *hilA* is the apparent integration point for a variety of signals that control the expression of the invasion genes. Two SPI1 encoded proteins, HilC (SirC or SprA) and HilD, both members of the AraC/XylS family of transcriptional regulators, induce expression of *hilA* (Eichelberg et al., 1999b; Rakeman et al., 1999; Schechter et al., 1999). Loss of HilD decreases expression of *hilA* ca. tenfold under SPI1 inducing conditions, whereas a mutation of *hilC* reduces expression of *hilA* ca. twofold (Lucas and Lee, 2001). HilC and HilD bind to the *hilA* promoter region, and binding is believed to induce the expression of *hilA* (Schechter et al., 1999; Schechter and Lee, 2001; Olekhovich and Kadner, 2002). HilC and HilD also induce expression of the *inv/spa* operon, and hence *invF*, independent of HilA (Eichelberg et al., 1999b; Rakeman et al., 1999; Akbar et al., 2003).

We have recently identified two regulatory proteins, termed RtsA and RtsB, which are encoded in an operon located on a 15-kb island inserted near the tRNA^{Phe} gene (Ellermeier and Slauch, 2003). RtsA belongs to the AraC/XylS family of regulators and RtsB is a helix-turn-helix DNA binding protein. RtsA, like its paralogs, HilC and HilD, increases expression of *hilA* by direct binding of RtsA to the *hilA* promoter. RtsA also induces expression of *hilD*, *hilC* and the *invF* operon. In addition to activating SPI1-related genes via induction of InvF, RtsA is capa-

ble of activating, independently of HilA or InvF, at least one effector gene, *slrP* (Ellermeier and Slauch, 2003), and *dsbA*, which encodes a periplasmic disulfide bond isomerase required for function of the SPI1 TTSS (Ellermeier and Slauch, 2004). RtsB represses expression of the flagellar genes by binding to the *flhDC* promoter region. Repressing production of the positive activators FlhDC decreases expression of the entire flagellar regulon. Thus RtsA and RtsB appear to coordinate induction of invasion and repression of motility in the small intestine.

We propose that RtsA, HilC and HilD act as a feed-forward loop to activate *hilA* and hence the SPI1 TTSS (C. D. Ellermeier et al., unpublished hypothesis). These three homologous AraC-like regulators are seemingly redundant, in that they can each independently activate *hilA*. However, they each can also independently activate themselves and each other, e.g., RtsA activates *rtsAB*, *hilC*, *hilD*, etc. Thus, activation of any of the three should activate the entire system. Indeed, we have shown that at least two of these regulators must be present for significant induction of SPI1 either in the laboratory or during infection (C. D. Ellermeier et al., unpublished observation). AraC-like regulators often interact with a small molecule, like arabinose, to activate transcription. Possibly, RtsA, HilC, and HilD each respond to an independent signal to activate SPI1, but what these signals are is not clear.

Global Regulators of the SPI1 TTSS

Genetic studies have identified a wide array of regulatory proteins encoded outside of SPI1 that impinge on expression of *hilA*. This includes several two-component regulatory systems (for a review, see Hoch and Silhavy [1995] and Bijlsma and Groisman [2003]). PhoPQ, a significant regulator of virulence and physiology (Groisman, 2001), represses expression of the SPI1 TTSS (Behlau and Miller, 1993; Pegues et al., 1995) in response to low magnesium concentrations (Chamnongpol et al., 2003). The PhoBR two-component regulatory system also represses expression of *hilA* (Lucas et al., 2000; Lucas and Lee, 2001), presumably in response to its normal signal, low extracellular phosphate ion concentration. Mutations that disrupt the osmoregulatory two-component system OmpR/EnvZ reduce expression of *hilA* but do not alter the osmoregulation of *hilA* (Lucas and Lee, 2001). SirA (the response regulator)/BarA (the sensor kinase) is a two-component regulatory system required for maximal expression of *hilA*; *sirA* mutations decrease expression of *hilA* ca. tenfold (Johnston et al., 1996; Ahmer et al., 1999b; Rakeman et al., 1999; Lucas and Lee, 2001). BarA/SirA have

recently been implicated in controlling SPI1 gene expression in response to bile (Prouty and Gunn, 2000).

In *E. coli* the SirA/BarA homologues, UvrY/BarA, are involved in a regulatory loop with *csrAB* (Suzuki et al., 2002), which encode a protein-RNA pair that function as both positive and negative regulators of gene expression. CsrA is a 61-amino acid protein that can directly bind mRNA transcripts tagging them for degradation (Romeo, 1998). The RNA partner *csrB* is a 360-nucleotide RNA that antagonizes the activity of CsrA by binding 18 CsrA molecules (Romeo, 1998). In the absence of *csrB*, CsrA is free to bind mRNA and tag these transcripts for degradation (Romeo, 1998). Either a null mutation in *csrB* or increased expression of *csrA*⁺ decreases expression of *hilA* (Altier et al., 2000a; Altier et al., 2000b). Also, a *csrB* null mutant was observed to decrease the steady state levels of *hilC* and *hilD* mRNA (Altier et al., 2000a). Still unclear is whether this decrease is a direct effect of CsrA binding to the *hilC* and *hilD* transcripts and targeting them for degradation. A mutation in *csrA* also decreases expression of the invasion genes suggesting that CsrA can act as both a positive and negative regulator of *hilA* expression (Altier et al., 2000a).

Several other regulatory systems have been implicated in SPI1 regulation. A mutation in the gene *hilE* increases expression of *hilA* under SPI1 inducing and repressing conditions (Fahlen et al., 2000). HilE represses expression of *hilA* by interacting with HilD (Baxter and Jones, 2003). Indeed, recent data suggests that several, if not all, of the two-component systems feed into the HilD, HilC, RtsA regulatory network through HilD, perhaps via HilE (Baxter and Jones, 2003; C. D. Ellermeier et al., unpublished data).

Mutations in *sirB*, *lon*, *hupB*, *hha* and *fis* alter expression of *hilA* under both *hilA* inducing and repressing conditions (Johnston et al., 1996; Fahlen et al., 2000; Fahlen et al., 2001; Wilson et al., 2001; Takaya et al., 2002). Hha and Lon decrease expression of *hilA* while Fis, IHF, and SirB increase expression of *hilA*. Indeed, Lon has recently been implicated in downregulating HilA after invasion has taken place (Boddicker and Jones, 2004). A previously unidentified PhoP-activated gene (*pag*) has also been shown to negatively regulate *hilA* expression (Fahlen et al., 2000). With the exception of Hha, which binds to the *hilA* promoter region, it remains mechanistically unclear how these gene products control expression of *hilA* (Fahlen et al., 2001). Several studies have identified the class 3 flagellar protein FlhZ as an activator of *hilA* expression (Eichelberg and Galan, 2000; Lucas et al., 2000; Iyoda et al., 2001), although still unclear is how

FlhZ activates expression of *hilA*. A number of mutations in the SPI2 TTS apparatus repress expression of *hilA* (Deiwick et al., 1998). The molecular mechanism and physiological relevance of these mutations on expression of *hilA* also remains unclear.

Gastroenteritis

The mechanism by which serovar Typhimurium causes gastroenteritis is not completely clear, but the current model suggests it is caused by inflammation, increased fluid accumulation within the small intestine, and polymorphonuclear leukocyte (PMN) influx into the small intestine (McCormick et al., 1995; Darwin and Miller, 1999b; Zhang et al., 2003). Most virulence studies on serovar Typhimurium use a mouse model of infection. One caveat is that a serovar Typhimurium infection of a mouse (unlike that of a human) does not result in gastroenteritis or diarrhea. Therefore, several groups have used a calf model of infection to study how serovar Typhimurium causes gastroenteritis (Zhang et al., 2003). In calves, serovar Typhimurium causes diarrhea, inflammation of Peyer's patches, fluid accumulation in the small intestine, and PMN influx into the small intestine (Zhang et al., 2003). Clearly, mutants of the SPI1 TTSS are severely decreased in the ability to cause gastroenteritis in calves (Tsolis et al., 2000; Zhang et al., 2002), and specific SPI1 effector proteins have been implicated (Zhang et al., 2002; see SPI1 Effectors).

Various tissue culture systems have also been used to model the interaction of *Salmonella* with the intestinal epithelium, leading to a complex picture of potential disease mechanisms (Hurley and McCormick, 2003). Serovar Typhimurium strains are capable of inducing polarized epithelial cell lines to secrete the proinflammatory cytokine, IL-8, primarily from the basolateral side (McCormick et al., 1993). Secretion of IL-8 may form a gradient, which recruits PMNs to the lamina propria. Serovar Typhimurium induces PMN migration across the epithelial barrier by inducing the secretion of a pathogen-elicited epithelial chemoattractant (PEEC) on the apical side (McCormick et al., 1998). Other chemokines have also been detected (Hurley and McCormick, 2003). Interestingly neither *S. typhi* nor *S. paratyphi* elicit secretion of PEEC, nor do they promote transepithelial migration of PMNs in vitro, consistent with the limited diarrhea often observed in infections with these organisms (McCormick et al., 1995).

In nonpolarized epithelial cells, the injected SPI1 effectors SopE1, SopE2, and SopB (see Effectors) activate CDC42 and Rac1 leading to

not only cytoskeletal rearrangements, but also activation of NF- κ B and IL-8 production (Chen et al., 1996a; Hardt et al., 1998). In polarized cells, however, the target of these effectors is apparently Rac1 at the apical surface, and interaction stimulates cytoskeletal rearrangement but not activation of the signal cascade (Hobert et al., 2002). Thus, the effectors do not directly activate IL-8 production. However, effector-mediated CDC42 and Rac1 activation are required for IL-8 release at the basolateral surface of the polarized cells (Hobert et al., 2002).

NF- κ B and hence IL-8 are apparently stimulated by bacterial flagellin activating Toll-like receptor 5 (TLR5), which is only expressed on the basolateral surface of polarized cells (Gewirtz et al., 2001a; Hayashi et al., 2001). Serovar Typhimurium strains lacking flagellin such as a *fljC fljB* double mutant are severely decreased in their ability to elicit IL-8 secretion (Gewirtz et al., 2001b). Purified FliC added to the apical surface of polarized epithelial cells does not induce secretion of IL-8, while addition of FliC to the basolateral surface does (Gewirtz et al., 2001b). This suggests that epithelial cells are able to sense and respond to invasive bacteria by sensing the presence of the flagellin on the basolateral surface without responding to commensal organisms normally present on the apical surface.

PEEC is secreted apically by the polarized epithelial cells and directs PMN migration across the epithelial monolayer (McCormick et al., 1998). A *sipA* mutant (see SPI1 Effectors) was shown to be unable to elicit PEEC secretion (Lee et al., 2000b). Interestingly, translocation of SipA is not required because the addition of purified SipA is sufficient to elicit transepithelial migration of PMNs (Lee et al., 2000b). Mutation of *sipA* does not affect *Salmonella* induced secretion of IL-8. These data suggest that SPI1 effectors and flagellin act in concert, but at distinct steps, to initiate an inflammatory response at the intestinal mucosa.

SPI1-Independent Mechanisms of Breaching the Epithelial Barrier

Although serovar Typhimurium utilizes the SPI1 TTSS to induce invasion of nonphagocytic epithelial cells, it is not absolutely required to produce a systemic infection, suggesting that multiple pathways exist by which serovar Typhimurium can cross the epithelial barrier (Jones et al., 1994; Penheiter et al., 1997). Vazquez-Torres et al. (1999) reported that serovar Typhimurium could be transported across the epithelial barrier within CD18⁺ cells. They utilized a serovar Typhimurium strain containing an *invG* mutation, which blocks SPI1 type III secretion and invasion, and an *lpf* mutation, which should block

targeting of *Salmonella* to M cells (Baumler et al., 1996b; Baumler et al., 1997b). Whereas these mutations clearly reduce virulence, the mutant bacteria could be found in the bloodstream within 15 min after an oral infection (Vazquez-Torres et al., 1999). The authors showed that CD18 knock-out mice, when compared to wild-type mice, had decreased numbers of serovar Typhimurium in their spleen after an oral infection with the mutant bacteria, whereas after intraperitoneal (IP) infection the CD18 knock-out mice actually contained increased numbers of serovar Typhimurium in the spleen (Vazquez-Torres et al., 1999). This suggests that CD18 cells (neutrophils?) are responsible for the transport of these mutant serovar Typhimurium from the small intestine to the spleen. That CD18⁺ cells actually transport serovar Typhimurium across the epithelial cells has been suggested but not demonstrated (Vazquez-Torres et al., 1999). Strains containing *invA lpfC* double mutants can still be phagocytosed by M cells and passed to the underlying lymph tissue. Therefore, CD18⁺ cells may not need to cross the membrane to transport serovar Typhimurium. Another model is that the M cells phagocytize serovar Typhimurium and pass them to the CD18⁺ cells in the underlying lymph tissue of the Peyer's Patch. The CD18⁺ cells can then disseminate serovar Typhimurium to the target organs. Interestingly the authors showed that SPI1 mutants were unable to elicit an IgA mucosal immune response but were fully capable of eliciting a systemic IgG response (Vazquez-Torres et al., 1999). This does suggest that the Peyer's patches were bypassed in this situation.

Peyer's Patch Survival

In mice, serovar Typhimurium preferentially invade and colonize the distal ileal Peyer's patches (Carter and Collins, 1974; Jones et al., 1994; Wallis and Galyov, 2000), specialized lymphoid tissue designed to sample intestinal antigens and lead to an immune response that preferentially involves the production of IgA. Invasion results in destruction of the M cell and inflammation of the Peyer's patch (Jones et al., 1994). Recent data suggest that *Salmonella* is primarily found within Peyer's patch dendritic cells (Hopkins and Kraehenbuhl, 1997; Hopkins et al., 2000). Survival of serovar Typhimurium within dendritic cells does not appear to require the same virulence factors required for macrophage survival (Niedergang et al., 2000; see Survival within Macrophages). Other data suggest that *Salmonella* induction of necrosis in macrophages (Brennan and Cookson, 2000; Watson et al., 2000), mediated by the SPI1 effector protein SipB interaction with caspase-1, is critical for

growth in Peyer's patches (Chen et al., 1996b; Monack et al., 1996; Monack et al., 2000; Hersh et al., 1999; Lundberg et al., 1999). Caspase-1 or ICE (interleukin-1 β -converting enzyme) is required for processing of IL-1 β but is also capable of inducing necrosis, an inflammatory event. In caspase-1 deficient mice, bacteria were not recovered in significant numbers from the Peyer's patches or any deeper tissue (Monack et al., 2000). In ligated-loop experiments, the bacteria traverse the M cells of caspase-1 deficient mice. Also, there is no apparent difference in infection of wildtype versus caspase-1 knockout mice when the bacteria are injected intraperitoneally. Thus, caspase-1 is required for serovar Typhimurium to propagate in the Peyer's patch. We have previously shown that *gipA*, encoded on the Gifsy-1 prophage, is specifically required for growth in the Peyer's patch (Stanley et al., 2000). These results suggest that the bacteria sense and respond to the particular environment of the Peyer's patch and that a subset of virulence factors will be required to grow in this tissue.

The bacteria continue to propagate in the Peyer's patch. Whether this growth is extracellular or intracellular is not clear. Also, if growth of serovar Typhimurium is intracellular, what eukaryotic cell types are involved is unknown. Serovar Typhimurium could potentially interact with any cell type present in the Peyer's patch. In addition to dendritic cells and macrophages, neutrophils are clearly present in the Peyer's patch after initial infection (Monack et al., 2000). This is consistent with the fact that caspase-1-mediated necrosis should initiate inflammation. Also known is that serovar Typhimurium can invade B and T cells in tissue culture (Verjans et al., 1994). Presumably, the SPI1 type III secretion system is no longer induced in the Peyer's patch environment and subsequent intracellular growth does not require this system. Serovar Typhimurium possesses a second type III secretion system encoded on SPI2 (see below). This system is induced during and is required for intracellular growth in macrophages in vitro (Cirillo et al., 1998). Serovar Typhimurium strains mutant in SPI2 propagate in the Peyer's patch, although the numbers of bacteria are slightly reduced compared to the wildtype strain. These SPI2 mutants are incapable of surviving beyond the Peyer's patch tissue (Cirillo et al., 1998).

Survival within Macrophages

After propagating in the Peyer's patch, serovar Typhimurium is spread systemically to target organs, particularly the spleen, liver, and bone marrow (Collins, 1970; Carter and Collins, 1974). In mice, the bacteria continue to increase in

numbers, eventually causing death. An important aspect of systemic growth is the ability of serovar Typhimurium to survive in macrophages (Collins, 1970; Carroll et al., 1979). The role of neutrophils in *Salmonella* infection is more controversial (Cheminay et al., 2004). Several lines of evidence support the macrophage as the primary site of replication during systemic infections (Richter-Dahlfors et al., 1997; Salcedo et al., 2001), and serovar Typhimurium mutants that cannot grow in tissue culture macrophages are avirulent (Fields et al., 1986; Buchmeier and Heffron, 1989). During growth within macrophages, serovar Typhimurium replicates within a specialized *Salmonella* containing vacuole (SCV; Holden, 2002). Long tubular structures called "*Salmonella* induced filaments" ("Sifs"; Garcia-del Portillo et al., 1993) are also evident. These filaments are rich in lysosomal glycoproteins, extend from the SCV, and require microtubule formation (Stein et al., 1996). The SCV and Sifs are actively maintained by serovar Typhimurium and their formation is dependent on several virulence factors.

Phagocytes normally kill engulfed bacteria using a battery of toxic substances. Phagosomes fuse with lysosomes, which contain hydrolytic degradative enzymes, antimicrobial peptides, and NADPH-dependent oxidase, which produces superoxide (Clark, 1999). Activated macrophages also produce nitric oxide, generated from arginine and oxygen by the inducible nitric oxide synthase (iNOS; Miller and Britigan, 1997). The nitric oxide can react with superoxide to produce highly toxic peroxynitrite (Miller and Britigan, 1997; Storz and Imlay, 1999). Other reactive oxygen species (ROS) and reactive nitrogen species (RNS) are also generated (Storz and Imlay, 1999). Serovar Typhimurium apparently has the ability to both prevent the induction or delivery of these enzymes to the SCV and survive these insults once induced (Ernst et al., 1999; Uchiya et al., 1999; Vazquez-Torres et al., 2000; Gallois et al., 2001).

Generation of superoxide by macrophages is dependent upon NADPH-dependent oxidase (phox). Normally serovar Typhimurium blocks delivery of the NADPH-dependent oxidase by blocking phagosome lysosome fusion in a SPI2 TTSS-dependent manner (Gallois et al., 2001; Vazquez-Torres and Fang, 2001; see TTSS). Thus one mechanism by which serovar Typhimurium avoids death by superoxide is by blocking the delivery of the host enzyme responsible for its production.

The SPI2 TTSS Apparatus

Serovar Typhimurium possesses a second TTSS encoded on SPI2 (Hensel, 2000). In addition to

encoding proteins related to tetrathionate reductase and several genes of unknown function, the 40-kb locus encodes 31 ORFs organized into two operons that encode the secretion system apparatus (*ssa* genes), one operon encoding effector and chaperone proteins (*sse* and *ssc* genes, respectively) and an operon encoding the two-component regulatory system SsrAB (*ssr* for secretion system regulator; Hensel, 2000). SPI2 mutants are incapable of surviving beyond the Peyer's patch (Cirillo et al., 1998). This system is induced during intracellular growth in macrophages (Cirillo et al., 1998; Pfeifer et al., 1999), and apparently injects its effector proteins into the macrophage cytoplasm from within the phagosome (Hensel, 2000). The SPI2 apparatus structure has not been studied in detail and is, rather, deduced from the structure of homologous systems. The three "effector" proteins SseBCD function as the translocon, which is embedded in the phagosome membrane and required for translocation of other effectors.

SPI2 Effector Proteins and Chaperones

There are 13 known SPI2 effector proteins in addition to the translocon proteins SseBCD. These include the SPI2-encoded proteins SpiC, SseF and SseG. Effectors SifA, SifB, SlrP, SopD2, PipB and PipB2 are encoded on pathogenicity islands or islets, while SseI, SseJ, SspH1 and SspH2 are encoded on bacteriophage. SlrP and SspH1 are translocated by both the SPI1 and SPI2 TTSS. The specific functions of these various effector proteins are only beginning to be understood (Waterman and Holden, 2003). Approximately 11 additional genes have been identified as being regulated by SsrB, but these have not been shown to be translocated proteins (Worley et al., 2000).

The putative effector protein SpiC has been reported to block vesicular trafficking in *Salmonella* infected macrophages, thereby preventing the formation of mature phagolysosomes (Uchiya et al., 1999). Indeed, ectopic production of SpiC within a macrophage was capable of blocking phagosome-lysosome fusion (Uchiya et al., 1999). SpiC apparently interacts with the macrophage protein TassC, which has a suggested role in vesicular trafficking (Lee et al., 2002). However, SpiC is required for secretion of the translocon components SseBCD, and thus the translocation of all effectors (Freeman et al., 2002; Yu et al., 2002). SpiC is not essential for secretion of SPI2 effector proteins into the medium (Freeman et al., 2002; Yu et al., 2002). Thus, SpiC might have multiple roles.

The *sifA* gene was originally identified as essential for the formation of tubular membrane structures (Sifs) in *Salmonella*-infected epithelial

cells (Stein et al., 1996). These structures also occur in macrophages as extensions of the SCV. SifA production is dependent on SPI2 regulatory genes, and *sifA* mutants are defective for replication in macrophages and are attenuated in vivo (Beuzon et al., 2000; Guy et al., 2000). SseJ (Kuhle and Hensel, 2002; Ruiz-Albert et al., 2002; Freeman et al., 2003), SseF and SseG (Guy et al., 2000; Kuhle and Hensel, 2002) have also been implicated in Sif formation.

Regulation of the SPI2 TTSS

The expression of the SPI2 locus is induced during growth within macrophages (Valdivia and Falkow, 1997). Induction of SPI2 encoded genes is dependent upon a SPI2-encoded two-component regulatory system SsrAB (Cirillo et al., 1998). SsrA is a sensor kinase and SsrB is a response regulator. Induction of the SPI2 TTSS occurs at low pH (<6) and is independent of magnesium concentration and the PhoPQ two-component regulatory system (Deiwick et al., 1999; Miao et al., 2002). Expression of *ssrAB* itself is induced during growth within macrophages (Lee et al., 2000a). The layout of the *ssrA* and *ssrB* genes is unusual in that they are separately transcribed; SsrB activates its own promoter but not that of *ssrA* (Feng et al., 2003). Both transcripts are activated by the two-component regulatory system OmpR/EnvZ. Phosphorylated OmpR binds both the *ssrA* and *ssrB* promoter regions (Lee et al., 2000a; Feng et al., 2003).

The PhoPQ Regulon

The PhoPQ two-component system controls the expression of greater than 40 genes termed "pags" ("PhoP activated genes," which include the *phoPQ* operon) and "prgs" ("PhoP repressed genes," which include the SPI1 TTSS; Groisman, 2001). PhoQ, the sensor kinase, appears to autophosphorylate in response to low Mg^{+2} and Ca^{+2} concentrations (Soncini et al., 1996). PhoQ then phosphorylates PhoP, which activates or represses gene expression (Groisman, 2001). Null mutations in either *phoP* or *phoQ* increase the LD₅₀ ca. 5 logs after IP infection (Miller et al., 1989). Constitutively active *pho* mutants also decrease virulence after both oral and IP infections (Miller and Mekalanos, 1990), suggesting that the appropriate regulation of virulence genes is important for survival.

Groisman (2001) suggests that the PhoPQ regulon is responsible for several overlapping functions: adaptation to low Mg^{+2} , regulation of virulence, including regulation of genes acquired by horizontal gene transfer, and modification of the cell envelope. PhoPQ activate two of the three genes or operons that encode Mg^{+2} trans-

porters: *mgtA* and *mgtCB*. MgtA and MgtB are each members of the P-type ATPase family of ion transporters (Moncrief and Maguire, 1999). MgtC, encoded with MgtB is essential for virulence but is apparently not involved in Mg^{+2} transport (Blanc-Potard and Groisman, 1997; Moncrief and Maguire, 1998). Other PhoP-activated genes with known biochemical functions include *pagP* (which encodes an outer membrane protein responsible for incorporating palmitate into lipid A, imparting resistance to the antimicrobial peptide C18G; Bishop et al., 2000); *pgtE* (which encodes an outer membrane protease that can degrade antimicrobial peptides; Guina et al., 2000); and *pcgL* (which encodes a D-Ala-D-Ala dipeptidase; Mouslim et al., 2002). PhoP represses expression of the SPI1 secretion system (see SPI1 TTSS) during intracellular growth. The molecular functions of most of the PhoP-regulated genes are unknown.

PhoPQ activate expression of the *pmrD* gene, whose product posttranscriptionally activates the PmrAB two-component regulatory system (Gunn and Miller, 1996; Groisman, 2001). PmrAB then regulates expression of a number of genes that are involved in resistance to antimicrobial peptides, such as polymyxin B (Gunn et al., 2000). One resistance mechanism is modification of LPS. PmrA induces expression of *pmrE* and *pmrHFIJKLM*, which encode proteins that synthesize a modified lipid A by adding 4-aminoarabinose (Gunn et al., 1998). This results in a more positively charged LPS, which is thought to inhibit the actions of negatively charged antimicrobial peptides and also compensates for loss of Mg^{+2} , required to counteract the negative charges on the LPS (Groisman et al., 1997; Groisman et al., 1998).

Additional Loci Required for Macrophage Survival

Several other *Salmonella* loci are implicated in macrophage survival. The *spv* operon located on the *Salmonella* virulence plasmid is required for systemic infection (Guiney et al., 1995) and encodes SpvB, which functions by ADP-ribosylating actin (Lesnick et al., 2001). SlyA is a transcriptional regulator that has been implicated in resistance to oxidative stress, macrophage survival, and virulence in the mouse model (Buchmeier et al., 1997; Watson et al., 1999). Recent studies (Spory et al., 2002; Stapleton et al., 2002) have identified a number of SlyA-regulated genes in *E. coli* and serovar Typhimurium, including a variety of stress response loci. Thus, the SlyA regulon apparently overlaps with the regulons of both the heat shock σ factor, RpoH, and the general stress response σ factor, RpoS. Null mutations in the *sspJ* gene confer sensitivity

to the redox cycling agent menadione and a virulence defect in macrophages and the animal model of infection (Van der et al., 2001; Van Diepen et al., 2002). The biochemical function of SspJ is yet to be determined. The periplasmic superoxide dismutase SodCI, encoded on the lysogenic bacteriophage Gifsy-2, is required for resistance to phagocytic superoxide (Ho et al., 2002; Uzzau et al., 2002; Krishnakumar et al., 2004). Certain auxotrophic mutations also attenuate macrophage survival and virulence in the animal model (Fields et al., 1986), suggesting that SCVs are limiting for some nutrients.

The Carrier State and Gallbladder Survival

Approximately 1–4% of individuals infected with *S. typhi* and 0.5% of individuals infected with serovar Typhimurium develop a chronic carrier state infection (Miller and Pegues, 2000). In these chronic infections, the bacteria reside in the gallbladder and development of this state is often associated with abnormalities such as gallstones (Prouty et al., 2002a). Hypothetically, the ability to both resist high concentrations of bile and form biofilms on surfaces such as gallstones is important for establishing the carrier state (Van Velkinburgh and Gunn, 1999; Prouty et al., 2002a; Prouty et al., 2002b). The PhoPQ regulatory system is required for resistance to high concentrations of bile, although none of the known PhoP-regulated loci are individually necessary (Van Velkinburgh and Gunn, 1999). Indeed, the presence of bile decreases transcription of the PhoP-activated gene *pagC* in a PhoP-independent fashion (Prouty et al., 2004b). Other members of the PhoP regulon are apparently unaffected at the transcriptional level. The *yciGFE-katN* operon, which encodes an acid shock protein (YciE) and a non-heme catalase (KatN), is induced in the presence of bile. Also, evidence shows that both the flagellar regulon and the SPI1 TTSS are repressed when bile was added to the medium. Decreased expression of SPI1 is consistent with a previous report that invasion of epithelial cells is decreased in the presence of bile (Prouty and Gunn, 2000). The *marRAB* operon is also induced, the products of which transcriptionally regulate a variety of genes leading to a multiple antibiotic-resistance phenotype, including the *acrAB* operon, which encodes an efflux pump (Prouty et al., 2004a) that likely expels bile from the cytoplasm. AcrAB (Prouty et al., 2004a) and TolQRA, involved in outer membrane integrity and colicin and phage translocation (Prouty et al., 2002b), are required for bile-resistance.

Numerous bacterial species are capable of forming biofilms, or communities of microorganisms, which are often more resistant to

antimicrobial agents, desiccation and harsh environments (Costerton et al., 1995; Davey and O'Toole, 2000). Serovars Typhimurium and Typhi are capable of forming biofilms on human gallstones only when they are grown in the presence of bile (Prouty et al., 2002a). Biofilm formation on gallstones requires LPS, flagella and LuxS, a potential quorum sensing regulator (Prouty et al., 2002a). Interestingly, fimbriae appear to play a negative role in biofilm formation, as a strain containing mutations in *lpfC*, *fim*, *pef* and *agf* actually form biofilms at a faster rate (Prouty et al., 2002a). Also surprisingly, *phoP* mutations enhanced biofilm formation, while the SPI1 TTSS and flagella were required (Prouty and Gunn, 2003). Taken together, these results indicate a complex interaction between bile resistance, gene induction, and biofilm formation.

Flagella

Most *Salmonella* species, with the exception of serovars Gallinarum and Pullarum, are motile. *Salmonella* motility is mediated by peritrichous flagella, which appear as long thin filaments usually numbering between 5–10 per cell (Macnab, 1996). The flagella structure is composed of nearly 40 gene products and can be separated into three parts, the basal body, a hook, and a long helical filament (Macnab, 1996; Macnab, 2003). The flagellar filament is constructed from ca. 20,000 subunits of a single protein, either FliC or FljB (see Phase Variation).

Flagellar regulation is complex and controlled on multiple levels. The greater than 40 genes involved in flagellar biosynthesis can be separated into three classes on the basis of their regulation. The *flhDC* genes make up the class 1 flagellar genes and encode for positive transcriptional regulators of class 2 flagellar genes, which include the *fliAZY*, *fliEFGHIJK* *fliLMNOPQR*, *flhBAE* and *flgABCDEFGHII* operons (Liu and Matsumura, 1994; X. Liu et al., 1995; Macnab, 1996). Still unclear is whether FlhDC can sense any environmental signal or whether activation of the class 2 genes is simply dependent on the posttranscriptional level of FlhDC expression. Numerous global regulatory systems feed into flagellar regulation at the level of FlhDC production (Shin and Park, 1995; Macnab, 1996; Ko and Park, 2000; Adams et al., 2001; Goodier and Ahmer, 2001; Wei et al., 2001; Clegg and Hughes, 2002; Lehnen et al., 2002; Ellermeier and Schlauch, 2003; Tomoyasu et al., 2003).

The class 2 gene product, FliA, is an alternative σ factor that is required for transcription of the class 3 flagellar genes, which include *flgMN*, *motABcheAW*, *tarcheRBYZ*, and *fliCDST* (Macnab, 1996). While FliA is required for maximal

expression of class 3 genes, it is not the sole regulator of class 3 gene expression. FlgM, a class 3 gene product, also regulates expression of class 3 genes by sequestering FliA and blocking activation of the class 3 genes (Gillen and Hughes, 1991; Chilcott and Hughes, 2000). Once the flagellar basal body has been assembled, FlgM is secreted by the assembled flagella, freeing FliA to activate expression of class 3 genes. This mechanism of regulation allows the bacteria to couple the regulation of the class 3 genes to the assembly of the flagella system (Chilcott and Hughes, 2000).

Recently the class 2 flagellar gene *fliZ* has been implicated in expression of the flagellar genes (Ikebe et al., 1999; Kutsukake et al., 1999). Mutants of *fliZ* decrease expression of the class 2 flagellar genes (Ikebe et al., 1999; Kutsukake et al., 1999). FliZ has also been reported to be a positive regulator of *hilA* expression (Eichelberg and Galan, 2000; Lucas et al., 2000; Iyoda et al., 2001). Still unclear is how FliZ increases expression of either the class 2 flagellar genes or *hilA*.

PHASE VARIATION OF THE FLAGELLIN SUBUNIT *Salmonella enterica* subsp. I, II, IIIa and VI are biphasic, capable of producing two antigenically flagellin subunits or H antigens. In serovar Typhimurium, these are encoded by the genes *fliC* and *fljB*, only one of which is expressed at any given moment (Macnab, 1996). The regulation of these two flagellins is controlled by a site-specific recombinase or DNA invertase Hin, which controls expression of *fljAB* by inverting the *fljAB* promoter (Macnab, 1996). When *fljAB* is in the off position, the *fljB* promoter is in the wrong orientation with respect to the *fljAB* genes, and without FljA, *fliC* is expressed, resulting in a flagellar filament constructed of the FliC subunit. When Hin inverts the *fljB* promoter, the *fljAB* genes are expressed and FljA represses transcription of *fliC* resulting in a flagellar filament constructed of the FljB subunit. The FliC and FljB proteins are functionally analogous to each other but are antigenically distinct (Macnab, 1996).

Although flagella are not essential for virulence of serovar Typhimurium in BALB/c mice (Lockman and Curtiss, 1990), they affect interaction with the host at multiple levels (Lockman and Curtiss, 1992; Gewirtz et al., 2001b; Ikeda et al., 2001; Schmitt et al., 2001). The FliC/FljB flagellin proteins interact with TLR5 on the basolateral surface of epithelial cells to activate the NF- κ B pathway in epithelial cells (Gewirtz et al., 2001a), leading to secretion of IL-8 and production of human β -defensin 2 (Gewirtz et al., 2000; Takahashi et al., 2001; see Gastroenteritis). FliC has also been shown to be a major CD4⁺

T-cell epitope in mice (McSorley et al., 2000). However, strains that produce only FljB are attenuated during systemic infection in a mouse model (Ikeda et al., 2001).

Epidemiology

NONTYPHOIDAL *SALMONELLA* Non-Typhi *Salmonella* are estimated to cause 1.4 million cases of gastroenteritis and enteric fever per year in the United States (Mead et al., 1999; Voetsch et al., 2004). This represents 10% of the total food-borne illness in this country and corresponds to an incidence rate of 12.3 cases per 100,000 population (Voetsch et al., 2004). More importantly, of the foodborne diseases, salmonellosis accounts for 26% of hospitalizations (15,000 per year) and 31% of deaths (400–600 per year) (Mead et al., 1999; Voetsch et al., 2004). The incidence of *Salmonella* food-borne disease is seasonal, with most infections occurring in the summer (Anonymous, 1997; D'Souza et al., 2004). The incidence of *Salmonella* infections apparently increased over the last several decades owing largely to the expanding size and centralization of modern agriculture. However, the number of infections per year has remained essentially constant since 1996 (Voetsch et al., 2004). Of course, non-Typhi *Salmonella* are a major cause of morbidity and mortality throughout the world, particularly in children under the age of 5 (Graham, 2002).

Salmonella infection is a reportable disease in the United States, but the numbers above are estimates. The CDC receives and characterizes 30,000–40,000 isolates per year. Of the ca. 32,300 isolates received in 2002, serovars Typhimurium, Enteritidis and Newport were the most prevalent, representing 22%, 16% and 13%, respectively (Centers for Disease Control and Prevention, 2002). The remaining serovars that individually represent >2% of isolates were Heidelberg (6.1%), Javiana (3.7%) and Montevideo (2.2%; Centers for Disease Control and Prevention, 2002). Twenty-five percent of the isolates were from patients under 5 years of age. Thirty-seven percent of isolates were evenly distributed among patients 10–49 years of age. The number of isolates from patients >50 years old steadily decreased with the age of the patient (Centers for Disease Control and Prevention, 2002). However, mortality and the proportion of patients who are hospitalized increase significantly in patients over 60 years of age (Kennedy et al., 2004).

A majority of cases are sporadic. However, outbreaks occur frequently. The two largest outbreaks of *Salmonella* in the United States occurred in 1) 1985 when approximately 175,000 people were infected with serovar Typhimurium

from contaminated pasteurized milk (Ryan et al., 1987), and 2) 1994 when approximately 224,000 people were infected with serovar Enteritidis from contaminated ice cream products (Hennessy et al., 1996). *Salmonella* has also been used as a bioterrorism agent. A total of 751 persons were infected with serovar Typhimurium in 10 restaurants in Oregon during October and September 1984 after members of a religious commune had intentionally contaminated salad bars (Torok et al., 1997).

Salmonella primarily live in the intestinal tracts of animals (see Habitat). Thus, most infections result from eating contaminated foods from animal origins including meat, poultry, eggs, and dairy products (Miller and Pegues, 2000). Other implicated sources include other animals and fruits and vegetables contaminated with animal feces (Sanchez et al., 2002; Voetsch et al., 2004). Contact with reptiles and amphibians accounts for 6% of human infections (Centers for Disease Control and Prevention, 2003c), including infection with non-subsp. I strains (see Taxonomy). Table 6 lists the most frequent *Salmonella enterica* serovars isolated from symptomatic or non-symptomatic major food animals submitted to the CDC in 2002 (Centers for Disease Control and Prevention, 2003d). Several trends are apparent. Clearly, the most frequent human isolates correlate with the serovars that are commonly found in all three of the major food animals (e.g., serovar Typhimurium). This is also evident in the increase in the frequency of serovar Newport isolates in both cattle (29-fold since 1997;

Table 6. Most frequent clinical and nonclinical isolates from major food animals.

Source	Serovar ^a	% Total isolates for each animal species	
		Clinical ^b	Nonclinical
Bovine	Agona	5	2
	Dublin	5	2
	Kentucky	3	10
	Meleagridis	1	11
	Montevideo	4	26
	Newport	29	2
Chicken	Typhimurium ^c	22	11
	Enteritidis	8	3
	Heidelberg	31	50
	Kentucky	18	14
	Typhimurium ^c	8	7
Porcine	Agona	4	9
	Choleraesuis	14	0
	Derby	17	53
	Typhimurium ^c	28	22

^aThe 3–5 most frequently isolated serovars for either clinical or nonclinical cases are shown.

^bClinical indicates that the animal was symptomatic.

^cIncludes variation Copenhagen.

From Centers for Disease Control and Prevention (2003d).

Centers for Disease Control and Prevention, 1998; Centers for Disease Control and Prevention, 2003d) and humans (2.8-fold since 1997; Centers for Disease Control and Prevention, 2003d). However, this correlation is not strict, indicating definite genetic differences among strains, some being more virulent for humans. Indeed, some serovars are “host adapted” (see Habitat). For example, serovar *Choleraesuis* is a significant pathogen of pigs, but is rarely isolated from human patients (21 of 32,308 isolates in 2002; Centers for Disease Control and Prevention, 2003d).

Consistent with the role of meat products as a source of *Salmonella* infection, the pathogen is routinely recovered from meat samples from United States retail outlets. In several studies, *Salmonella* was recovered from 10–50% of chicken samples (Bokanyi et al., 1990; Izat et al., 1991; Simmons et al., 2003; Rigney et al., 2004), 24–30% of turkey samples (White et al., 2001; Rigney et al., 2004), 10–16% pork products (Duffy et al., 2001; White et al., 2001), and 4–19% of beef samples (White et al., 2001; Fraticchio, 2003; Rigney et al., 2004).

Hard shell eggs are an increasingly important source of *Salmonella* infection. This is due to the emergence of serovar Enteritidis beginning in the 1970s (Guard-Petter, 2001; Centers for Disease Control and Prevention, 2003b). This serovar has been the second leading cause of human infection in the United States and indeed surpassed serovar Typhimurium as the leading cause during the mid-1990s (Centers for Disease Control and Prevention, 2003d). Serovar Enteritidis is unique in that it can infect the ova of hens and can be deposited in eggs before the shell is formed (Guard-Petter, 2001). Inadequate refrigeration during shipment and storage of eggs, and incomplete cooking, allow infection.

The infective dose for foodborne *Salmonella* is difficult to determine and is likely to vary with strain, source (e.g., the particular food matrix could differentially protect from stomach acid), and the underlying health of the individual (Coleman and Marks, 2000; Coleman et al., 2004). Data on infective dose come from both volunteer studies and outbreaks. An analysis of various studies prior to 1982 suggested that the infective dose was $<10^3$ organisms (Blaser and Newman, 1982). More recent data from outbreaks suggest that the infective dose is surprisingly low. Contaminated paprika led to an outbreak involving several serovars in Germany in 1993. The infective dose was estimated to be 4–45 organisms giving an attack rate of 1 in 10,000 exposed individuals (Lehmacher et al., 1995). Analysis of ice cream samples from the same lots that led to the 1994 outbreak of serovar Enteritidis in the Midwest (Hennessy et al.,

1996), particularly single serving pre-packaged ice cream cones, suggested that the infective dose was 28 cells (Vought and Tatini, 1998). Both of these studies benefited from the fact that the nature of the food, the dried paprika and the frozen ice cream, preserved the viable organisms probably minimizing the change in number from the time of infection to analysis.

The *Salmonella*, like many bacterial pathogens, are becoming increasingly resistant to antibiotics (Parry, 2003). Characterization of isolates received by the CDC in 2001 (Centers for Disease Control and Prevention, 2003a) indicated that 51% of the serovar Typhimurium strains were resistant to at least one of the tested antibiotics and 35% were resistant to at least five antibiotics, most commonly ampicillin, chloramphenicol, streptomycin, sulfamethoxazole and tetracycline. This multidrug resistant phenotype is indicative of serovar Typhimurium strain DT104, for example, which has recently disseminated worldwide (Davis et al., 2002). Among serovar Enteritidis isolates, 14% were resistant to at least one antibiotic and 1% were resistant to at least five antibiotics (Centers for Disease Control and Prevention, 2003a). For serovar Newport, 35% were resistant to at least one antibiotic while 25% were resistant to at least eight antibiotics. In 1996, none of these multidrug-resistant isolates of serovar Newport were detected (Centers for Disease Control and Prevention, 2003a).

SEROVARS TYPHI AND PARATYPHI Serovars Typhi and Paratyphi are human specific pathogens. Thus, infection results from ingestion of water or food contaminated with human feces or close contact with an individual who has typhoid fever or is a chronic carrier (Miller and Pegues, 2000). Because of good public water and sewer systems, typhoid fever is rare in the United States, with an estimated 825 cases per year (Mead et al., 1999). Greater than 70% of these cases are in people who acquired the infection upon visiting an endemic area (Mead et al., 1999). However, outbreaks do occur in the United States, for example, from imported contaminated fruit (Katz et al., 2002), or from food service workers who are chronic carriers (Lin et al., 1988; Birkhead et al., 1993).

Worldwide, typhoid fever is a major health problem with an estimated 17 million cases per year resulting in 600,000 deaths (Pang et al., 1998). The infection is particularly prevalent in Asia and Africa (Pang et al., 1998) with rates as high as 980 per 100,000 population in Delhi, India, for example (Parry et al., 2002). Infection is reportedly highest in 3–19 year-olds (Pang et al., 1998), but more recent data suggest that 44–54% of infections occur in children under 5 years

of age (Graham, 2002). Reliable data is difficult to attain because of limited health care, public health infrastructure, and microbiological work-up in many of these developing nations.

The case fatality rate for untreated typhoid fever is 10–20%, but the advent of antibiotic treatment has reduced the fatality rate to less than 1% (Miller and Pegues, 2000; Maskalyk, 2003). Chloramphenicol has historically been the drug of choice, but resistance to chloramphenicol, ampicillin, and trimethoprim/sulfamethoxazole has been rising since the 1980s with up to 65% of strains isolated in India being multidrug resistant, for example (Pang et al., 1998). Fluoroquinolones are very effective (Parry et al., 2002), but resistance to these drugs is also being seen (Threlfall, 2002).

Disease

NONTYPHOIDAL *SALMONELLA* Infection by non-typhoid *Salmonella* usually results in self-limiting acute gastroenteritis (Shere et al., 1998; Miller and Pegues, 2000). After an incubation period of 6–48 h, there is often an onset of nausea and vomiting followed by abdominal pain and loose, watery diarrhea. The extent of diarrhea is variable, and blood and mucous in the stool are not uncommon. The abdominal pain can range from colicky discomfort to pseudoappendicitis. Approximately 50% of patients will have a slight fever ($<39^{\circ}\text{C}$) and chills but body temperature will return to normal in 1–2 days. The diarrhea lasts 3–7 days, although organisms can be shed for 4–5 weeks; longer in neonates. Approximately 6% of patients will develop Reiter's syndrome or reactive arthritis (Barth and Segal, 1999), most likely if the individual expresses HLA-B27 (Yu and Kuipers, 2003). Diagnosis is based on history and stool culture (see Isolation). Patients with simple gastroenteritis do not require treatment other than oral rehydration therapy. Indeed, the vast majority of these patients will not seek medical treatment and will never confirm that they were infected with *Salmonella*; hence only a small fraction of *Salmonella* cases are actually reported.

In addition to simple gastroenteritis, infection with non-Typhi *Salmonella* can be more severe, resulting in bacteremia, fever, or other complications (Shere et al., 1998; Miller and Pegues, 2000; Vugia et al., 2004). Certain individuals are particularly susceptible to more severe *Salmonella* infection, including those <1 year-old, the elderly, and immunocompromised patients, especially HIV infected patients, who often suffer from recurrent *Salmonella* bacteremia. One to four percent of immunocompetent individuals and an increased percent of those with weakened immune systems have sustained bacteremia and

fever. Once the infection has become systemic, the bacteria can colonize, albeit rarely, essentially any tissue in the body (Shere et al., 1998), including bone, meninges, lungs, and brain. *Salmonella* is a minor, but not insignificant cause of endocarditis, particularly in cases involving structurally abnormal heart valves. The bacteria are also responsible for a significant fraction of infective aortic aneurysms, indicative of the predilection of *Salmonella* to infect vascular tissue. These vascular infections have a high mortality rate (Fernandez Guerrero et al., 2004). The patients with significant bacteremia and extraintestinal infections are the most likely to seek medical care, and antibiotic treatment is warranted.

SEROVARS TYPHI AND PARATYPHI Serovars Typhi and Paratyphi are host adapted to humans, causing classic typhoid (or paratyphoid) fever (Shere et al., 1998; Miller and Pegues, 2000). After an incubation period of 5–21 days, some patients will have diarrhea and pain that may last several days. Individuals with or without diarrhea then develop fever that rises over 2–3 days to $39\text{--}40^{\circ}\text{C}$. Other symptoms can include chills, myalgias, abdominal pain, headache, cough, sore throat, and “rose spots,” a maculopapular rash seen on the trunk of 30% of patients. Psychosis and confusion occur in 5–10% of patients. Constipation is not uncommon. Perforation of the terminal ileum or proximal colon occurs in 3–10% of patients and is a significant cause of mortality. Symptoms are more severe in Typhoid fever versus Paratyphoid fever and are more severe in infants. For those untreated patients that survive, symptoms last approximately 4 weeks, although weakness may be evident for months. Ten percent of individuals will suffer a relapse. One to four percent of patients will develop long-term carriage (see Carrier State). Diagnosis is based on isolation of the bacteria, usually from blood or stool (see Isolation). Antibiotic treatment (see Epidemiology) significantly reduces the mortality rate and the duration of fever.

Vaccination against typhoid is recommended for travelers to endemic areas and for laboratory personnel who work with serovar Typhi (Miller and Pegues, 2000). There are three commercially available typhoid vaccines: a heat-phenol inactivated parenteral vaccine, an oral live attenuated Ty21a vaccine, and a more recent purified Vi capsular parenteral vaccine. All three have shown variable efficacies from approximately 45–95%. The heat-killed vaccine has the potential for more serious side effects than the other two. The Vi vaccine is gaining support and is being suggested for more widespread use (Pang et al., 1998). A new conjugate Vi vaccine is particularly promising (Lin et al., 2001; Mai et al., 2003).

DISEASE IN ANIMALS The *Salmonella* live primarily in the intestines of animals and cause significant disease in these hosts. These include the major agricultural animals and, therefore, *Salmonella* has significant consequences for production. The various serovars can be host adapted or restricted and, as is seen in humans, the nature and degree of disease is dependent on the specific serovar and host involved. Animals can be chronically infected and serve as important sources of organisms, or the infections can be acutely lethal. For example, serovar Dublin causes diarrhea in young calves but can also cause abortion in pregnant cows with no other clinical symptoms (Santos et al., 2001). Serovar Choleraesuis causes enterocolitis or septicemia in swine. Serovar Gallinarium causes fowl typhoid, a persistent infection. Serovar Enteritidis infects the oviduct of chickens, often with no clinical symptoms, yet the eggs become infected prior to the deposition of the shell (Guard-Petter, 2001). This is an important source of infection for humans.

Applications

Detailed knowledge of *Salmonella* physiology, genetics, pathogenesis, and host immune response has made various attenuated serovar Typhimurium or serovar Typhi strains favorite candidates for live attenuated vaccines for delivery of exogenous antigens (e.g., Garmory et al., 2002; Garmory et al., 2003). The goal is to stimulate the mucosal immune response, the first line of defense against most pathogens.

A second major application of *Salmonella* is the Ames Test (Gee et al., 1994). Bruce Ames developed the concept that carcinogens can be assayed by measuring mutagenic activity in bacteria, rather than by directly testing carcinogenesis in animals. Compounds, usually after treatment with liver extract to mimic metabolism in the human body, are mixed with one of several serovar Typhimurium strains that are histidine-requiring auxotrophs. The number of prototrophic revertants is a measure of mutagenic potential of the compound.

The Genus *Klebsiella*

SYLVAIN BRISSE, FRANCINE GRIMONT AND PATRICK A. D. GRIMONT

Taxonomic History and Structure

Historical Developments

The genus *Klebsiella*, in the family Enterobacteriaceae, was named by Trevisan (1885) to honor the German microbiologist Edwin Klebs (1834–1913). The type species is *Klebsiella pneumoniae* (Schroeter, 1886; Trevisan, 1887). The first *Klebsiella* species ever described was a capsulated bacillus from patients with rhinoscleroma (Von Frisch, 1882). The organism was named “*Klebsiella rhinoscleromatis*” by Trevisan (1887).

Abel (1893) observed a capsulated bacillus, “*Bacillus mucosus ozaenae*” from the nasal secretion of patients with ozaena. The bacterium was later transferred to the genus *Klebsiella* as *K. ozaenae* (Bergey et al., 1925).

Friedländer (1882) described a bacterium from the lungs of a patient who had died of pneumonia. The organism was named “*Hyalococcus pneumoniae*” (Schroeter, 1889) and *Klebsiella pneumoniae* (Trevisan, 1887). Considerable confusion occurred for many years since the organism could not be objectively separated from the bacterium Escherich described as “*Bacterium lactis aerogenes*” (Escherich, 1885) and which was renamed “*Bacillus aerogenes*” (Kruse, 1896), “*Aerobacter aerogenes*” (Kruse, 1896), and later *Enterobacter aerogenes* (Hormaeche and Edwards, 1960). Both *K. pneumoniae* and “*Aerobacter aerogenes*” fermented many carbohydrates (often with gas production), gave a positive Voges-Proskauer reaction and reacted with *Klebsiella* capsular antisera. A step forward was taken when Møller (1955) introduced the decarboxylase tests. *Klebsiella pneumoniae* was defined as nonmotile and ornithine decarboxylase negative, whereas “*A. aerogenes*” was defined as motile or nonmotile and ornithine decarboxylase positive (Hormaeche and Edwards, 1958). To reduce confusion in communication, a new genus *Enterobacter* was formed (Hormaeche and Edwards, 1960) in which “*A. aerogenes*” was transferred as *E. aerogenes*. Historically, this separation was probably arbitrary (authentic strains being unavailable), but these

redescriptions and the designation of neotype strains solved the problem for most microbiologists. However, *E. aerogenes* is much closer to *Klebsiella* species than to *Enterobacter cloacae* on the basis of phenotypic traits and DNA relatedness (Bascomb et al., 1971; Brenner et al., 1972; Steigerwalt et al., 1976; Izard et al., 1980) and 16S rRNA sequence (Boye and Hansen, 2003). The transfer of *E. aerogenes* to the genus *Klebsiella* as *K. mobilis* has been proposed (Bascomb et al., 1971). Nomenclatural confusion remained for some time in the United Kingdom where a biogroup of *K. pneumoniae* was named “*Klebsiella aerogenes*” (Taylor et al., 1956). Cowan et al. (1960) subdivided *K. pneumoniae* sensu lato into *K. pneumoniae* (sensu stricto), “*K. aerogenes*,” “*K. edwardsii* subsp. *Edwardsii*,” and “*K. edwardsii* subsp. *Atlantae*.” Authentic or typical strains of *K. pneumoniae*, “*K. edwardsii*” and “*K. aerogenes*” cannot be differentiated by DNA relatedness or protein electrophoresis and thus belong to a single species, *K. pneumoniae* (Brenner et al., 1972; Jain et al., 1974; Ferragut et al., 1989). Although their biochemical patterns allow easy identification, *K. ozaenae* and *K. rhinoscleromatis* cannot be separated from *K. pneumoniae* by DNA relatedness (Brenner et al., 1972). For this reason, *K. ozaenae* and *K. rhinoscleromatis* were treated as subspecies of *K. pneumoniae* in the *Bergey's Manual of Systematic Bacteriology* (Ørskov, 1974).

Flügge (1886) described “*Bacillus oxytocus pernicius*” from old milk. This organism was named “*Aerobacter oxytocus*” (Bergey, 1923) and *Klebsiella oxytoca* (Lautrop, 1956). For many years, the existence of this indole positive species was questioned, and it was often considered a biogroup of *K. pneumoniae* (Edwards and Ewing, 1972; Ørskov, 1974). DNA relatedness studies showed *K. oxytoca* to be clearly distinct from *K. pneumoniae* (Jain et al., 1974; Brenner et al., 1977).

The use of carbon source utilization tests and DNA hybridization allowed the delineation and characterization of two new species primarily isolated from environmental samples: *K. terrigena* (Izard et al., 1981) and *K. planticola*

(Bagley et al., 1981). The species described as *K. trevisanii* (Ferragut et al., 1983) was found to be identical to *K. planticola* (Gavini et al., 1986). The name "*K. ornithinolytica*" was proposed for ornithine-positive, indole-positive strains of *Klebsiella* (Sakazaki et al., 1989). The distinctness of this bacterial group from *K. planticola* needs to be confirmed since different results have been obtained in another laboratory (Farmer et al., 1985).

The move of *K. planticola*, *K. ornithinolytica* and *K. terrigena* to a new genus, *Raoultella* was recently proposed (Drancourt et al., 2001). However, the validity of this proposal is dubious since phylogenetic analysis of 16S rRNA gene sequence did not provide strong support for the monophyly of *Raoultella* (Drancourt et al., 2001; Boye and Hansen, 2003) and since *rpoB* sequence data failed to group *Raoultella* species into a single cluster (Drancourt et al., 2001).

The agent of donovanosis, *Calymmatobacterium granulomatis*, was found to be very closely related to *Klebsiella pneumoniae* on the basis of the 16S rRNA gene sequence (Carter et al., 1999; Kharsany et al., 1999) and on the phosphate porin (*phoE*) gene sequence (Bastian and Bowden, 1996; Carter et al., 1999). *Calymmatobacterium granulomatis* was proposed to be transferred to the genus *Klebsiella* as *Klebsiella granulomatis* (Carter et al., 1999), a proposal that had also been made by Richens (1985) given the similarity of pathological aspects of *C. granulomatis*, *K. pneumoniae* subsp. *rhinoscleromatis* and *K. pneumoniae* subsp. *ozaenae*. However, whether *Klebsiella granulomatis* is a genomic species distinct from *K. pneumoniae* is unknown. Instead, partial *rpoB* sequencing (Drancourt et al., 2001) confirmed *phoE* findings that *K. granulomatis* is very close to *K. pneumoniae*. Thus, *K. granulomatis* may correspond to a subspecies of *K. pneumoniae*.

The genetic diversity of *K. pneumoniae* and *K. oxytoca* species has been investigated using *gyrA* and *parC* gene nucleotide diversity, random amplified polymorphic DNA (RAPD), and ribotyping (Brisse and Verhoef, 2001). Three sequence clusters, named "KpI," "KpII" and "KpIII," were evidenced within *K. pneumoniae*, which did not correspond to the known subspecies, and two sequence clusters, KoI and KoII, were found within *K. oxytoca*. The genetic distinctness of these five clusters was confirmed using amplified fragment-length polymorphism (AFLP; Jonas et al., 2004). Two *K. oxytoca* groups were also found on the basis of partial sequences of the *rpoB* and 16S rRNA genes and the chromosomal β -lactamase genes *bla_{OXY-1}* and *bla_{OXY-2}* (Granier et al., 2003b). These groups correspond to KoI and KoII, respectively (S. Brisse, unpublished observation). In addition, there is

evidence that more phylogenetic groups exist within *K. pneumoniae* (Jonas et al., 2004) as well as within *K. oxytoca* (Granier et al., 2003a). Utilization of D-adonitol as sole carbon source was found to differ between KpI (all strains being positive) and KpIII (all strains being negative), while KpII was heterogeneous in this respect. DNA-DNA reassociation studies will be needed to determine whether these *K. pneumoniae* and *K. oxytoca* phylogenetic groups represent distinct genomic species.

Taxonomic Structure

The taxonomic structure of the genus *Klebsiella* that is currently widely accepted is given below. Uncertain points that still need to be clarified are the distinction between *K. planticola* and *K. ornithinolytica* and the phylogenetic distinctness of *K. granulomatis* and *K. pneumoniae*. The inclusion of *E. aerogenes* as *K. mobilis* is not consensual. Note that the definitions of *K. pneumoniae* subspecies are based on pathogenesis criteria and not on genomic distinctness.

1. *Klebsiella pneumoniae* (Schroeter, 1886; Trevisan, 1887). The type strain is ATCC 13883 (=NCTC 9633, CDC 298-53, CIP 82.91). This species contains three subspecies:

- 1a. *Klebsiella pneumoniae* subspecies *pneumoniae* (Schroeter, 1886; Ørskov, 1984a). The type strain is the same as for the species.

- 1b. *Klebsiella pneumoniae* subspecies *ozaenae* (Abel, 1893; Ørskov, 1984a), "*Bacillus mucosus ozaenae*" (Abel, 1893). The type strain is ATCC 11296 (= NCTC 5050, CIP 52.211).

- 1c. *Klebsiella pneumoniae* subspecies *rhinoscleromatis* (Trevisan, 1887; Ørskov, 1984a); *Klebsiella rhinoscleromatis* (Trevisan, 1887). The type strain is ATCC 13884 (= NCTC 5046, CIP 52.210).

2. *Klebsiella granulomatis* (Aragão and Vianna, 1913; Carter et al., 1999). Basonym: *Calymmatobacterium granulomatis* Aragão and Vianna, 1913; Approved Lists, 1980). Other synonyms: "*Encapsulatus inguinalis*" (Bergey, 1923), "*Klebsiella granulomatis*" (Bergey et al., 1925), "*Donovania granulomatis*" (Anderson et al., 1944). No type culture is currently available.

3. *Klebsiella oxytoca* (Flügge, 1886; Lautrop, 1956); "*Bacillus oxytocus perniciosus*" (Flügge, 1886). The type strain is ATCC 13182.

4. *Klebsiella planticola* (Bagley et al., 1981). The type strain is ATCC 33531 (= V-236, CDC 4245-72, CIP 100751). *Klebsiella trevisanii* (Ferragut et al., 1983; Phenon K of Gavini et al., 1977) is a junior subjective synonym of *K. planticola* (Gavini et al., 1986).

5. *Klebsiella ornithinolytica* (Sakazaki et al., 1989). The type strain is ATCC 31898 (NIH 90-72). The CDC group called "*Klebsiella* Group 47" corresponds to this species (Sakazaki et al., 1989).

6. *Klebsiella terrigena* (Izard et al., 1981), phenon L (Gavini et al., 1977). The type strain is ATCC 33257 (= CIP 80-07, CUETM 77-176).

7. *Klebsiella mobilis* (Bascomb et al., 1971), *Enterobacter aerogenes* (Kruse, 1896; Hormaeche and Edwards, 1960). The type strain is ATCC 13048 (= NCTC 10006, CDC 819-56, CIP

60.86). *Klebsiella mobilis* (*Enterobacter aerogenes*) will not be treated below (except for purpose of differentiation).

8. *Klebsiella variicola* Rosenblueth et al., 2004. The type strain is F2R9 (= ATCC BAA-830 = CFNE 2004). Corresponds to phylogenetic group KpIII of Brisse and Verhoef (2001).

Isolation

Underlying Principles

Klebsiella spp. grow readily on ordinary media commonly used to isolate Enterobacteriaceae, e.g., nutrient agar, tryptic casein soy agar, bromocresol purple lactose agar, blood agar, as well as more differential plating media for Enterobacteriaceae, such as Drigalski agar, MacConkey agar, eosin-methylene blue agar (EMB), and bromo-thymol blue agar (BTB). *Klebsiella pneumoniae* and *K. oxytoca* colonies are lactose positive, more or less dome-shaped, 3–4 mm in diameter after overnight incubation at 30°C or 37°C, with a mucoid aspect and sometimes stickiness, depending on the strain and the composition of the medium. *Klebsiella planticola* and *K. terrigena* colonies are also lactose positive, 1.5–2.5 mm in diameter, dome-shaped, with a weakly mucoid aspect. *Enterobacter aerogenes* (*K. mobilis*) colonies often have the same morphology. *Klebsiella ozaenae*, *K. rhinoscleromatis* and occasionally *K. pneumoniae* K1 grow more slowly on the same media, yielding voluminous, rounded, very mucoid, translucent and confluent colonies in 48 h at 30°C or 37°C (Ørskov, 1981; Richard, 1982). Similar colonies indistinguishable from those of *Klebsiella* may be formed by other genera of the Enterobacteriaceae, particularly *E. coli* mucoid varieties with capsular K antigens (Kauffmann, 1949; Ørskov and Fife-Asbury, 1977).

Almost all *Klebsiella* strains grow in minimal medium with ammonium ions or nitrate as sole nitrogen source and a carbon source (see below) without growth factor requirement. Some *K. pneumoniae* K1 isolates require arginine or adenine or both as growth factors. *Klebsiella pneumoniae* subsp. *rhinoscleromatis* requires arginine and uracil. Growth factor requirements of *K. pneumoniae* subsp. *ozaenae* are not fully determined (leucine, cysteine and methionine are stimulatory; O. Bouvet and P. A. D. Grimont, unpublished observations). In these requirements, ornithine can replace arginine.

Klebsiella strains can be conserved at room temperature in meat extract semisolid agar, or at –80°C in a broth medium with 10–50% (v/v) glycerol, or freeze-dried.

Klebsiella granulomatis has not been grown axenically in artificial media. In vivo cultures in the yolk sac or brain of chick embryo have been

achieved. In vitro cultures use fresh mononuclear cells (Kharsany et al., 1997) or the Hep-2 human epithelial cell line (Carter et al., 1997).

Selective Media

Several selective differential media for the isolation and enumeration of *Klebsiella* spp. were proposed in clinical, industrial and natural environments. The ability to utilize citrate (Cooke et al., 1979) or *myo*-inositol (Legakis et al., 1976) has been applied to selective medium formulation. Resistance of *Klebsiella* spp. to methyl violet (Campbell and Roth, 1975), double violet (Campbell et al., 1976), potassium tellurite (Tomas, 1986), and carbenicillin (Thom, 1970) has been used in selective media.

Thom (1970) developed a medium based on the MacConkey agar in which lactose is replaced by inositol, with the addition of 100 µg of carbenicillin per ml. Bagley and Seidler (1978a) devised a similar medium with only 50 µg of carbenicillin per ml.

MacConkey-inositol-carbenicillin Agar (Bagley and Seidler, 1978a)

MacConkey agar base (Difco)	40 g
<i>myo</i> -Inositol	10 g
Distilled water to	1 liter

Autoclave at 121°C for 15 min, cool to 50°C in a water bath, add 0.05 g of carbenicillin dissolved in 5 ml of sterile distilled water, and mix and dispense into sterile Petri dishes. Keep at 4°C and use within three days.

About 95% of pink-to-red colonies were verified to be *Klebsiella* spp., whereas only 1% of yellow background colonies were *Klebsiella*.

Since about 10% of *Klebsiella* strains are susceptible to 50 µg per ml of carbenicillin, the antibiotic was replaced in the above formula by tellurite (K₂TeO₃; Tomas, 1986), which is a strong inhibitor of phosphate transport in *Escherichia coli*. Minimal inhibitory concentrations of tellurite were 100 or 200 µg per ml for *K. pneumoniae* subsp. *pneumoniae*, *K. oxytoca*, *K. planticola* and *K. terrigena*, 10 µg per ml for *K. pneumoniae* subsp. *ozaenae*, and 1–3 µg per ml for other Enterobacteriaceae (Tomas, 1986). MacConkey-inositol-potassium tellurite agar is prepared by suspending 40 g of MacConkey agar base in 1 liter of distilled water. The preparation is autoclaved at 121°C for 15 min, cooled to 50°C, then supplemented with filter sterilized *myo*-inositol (final concentration, 10 mM) and potassium tellurite (final concentration 3 µg/ml). After mixing, the medium is dispensed in Petri dishes. This medium keeps well at 4°C for more than two months (Tomas, 1986). In a field test, 77% of pink-to-red colonies were confirmed as *Klebsiella* spp. However, the efficiency of plating was about 1% (Dutka et al., 1987), and some *Kleb*-

siella strains may be too susceptible to tellurite to grow on this medium.

Wong et al. (1985) devised a minimal medium in which the carbon source is lactose and the nitrogen source is potassium nitrate. Inhibitory compounds were deoxycholate, neutral red, and crystal violet.

Minimal Medium with Lactose, Nitrate, Deoxycholate, Neutral Red and Crystal Violet (Wong et al., 1985)

Hot deionized water	800 ml
Lactose	5.0 g
Sodium deoxycholate	1.0 g
Na ₂ HPO ₄	0.7 g
KNO ₃	1.08 g
NaH ₂ PO ₄	0.3 g
MgSO ₄ · H ₂ O	0.2 g
MnSO ₄	0.1 g
FeCl ₂	0.005 g
ZnCl ₂	0.005 g
CoCl ₂	0.005 g
Mo(OH) ₂	0.005 g

Dissolve and filter through Whatmann no. 2 filter paper. Adjust pH to 6.8 with 1 N NaOH. Then add the following: neutral red (0.03 g), crystal violet (0.004 g), and Noble agar (15 g). Boil to dissolve the agar, autoclave at 121°C for 15 min, and cool and dispense in Petri dishes. Incubate inoculated plates at 35°C for 36 h.

On this medium, *K. pneumoniae* and *K. oxytoca* grow as convex, and 1- to 2 mm-diameter, rather mucoid pink-to-red colonies, or larger, more watery pale red colonies with a dark red center. Non-*Klebsiella* either fail to grow or give colorless colonies (Wong et al., 1985).

Bruce et al. (1981) devised an agar medium combining Koser citrate and raffinose (carbon sources) and ornithine and low pH (for ornithine decarboxylase).

Acidic Koser Citrate Medium with Ornithine and Raffinose (Bruce et al., 1981)

Agar (BBL)	20.0 g
Koser citrate (Difco)	5.7 g
Phenol red (5% in 50% ethanol)	10 ml
L-Ornithine	10.0 g
Raffinose	7.0 g

Adjust pH to 5.6 with 1 N HCl and autoclave the medium at 121°C for 15 min. Cool and dispense into Petri dishes.

Klebsiella strains grow as yellow mucoid colonies. Other members of the Enterobacteriaceae either do not grow or produce small colorless, pink, red or orange colonies.

For the isolation of *K. pneumoniae* and *K. oxytoca* from human feces, Van Kregten et al. (1984) have developed a medium based on the presence of two carbon sources, citrate and inositol, without inhibitor. The medium consists of Simmons citrate agar with 1% inositol. The medium can be stored at 4°C. *Klebsiella* spp. appear as yellow, dome-shaped, often mucoid colonies, whereas *E.*

coli appears as tiny, watery colonies. Apart from some *Enterobacter* strains, no other bacteria grow on the medium.

Identification

The general methods used for the identification of *Klebsiella* species and other Enterobacteriaceae can be found in Ewing (1986) and Farmer et al. (1980). However, other tests are extremely useful in enterobacterial taxonomy. These include carbon source utilization tests, glucose oxidation (in the presence or absence of added pyrroloquinoline quinone), gluconate- and 2-ketogluconate dehydrogenase tests (Bouvet et al., 1989), and tetrathionate reductase and β -xylosidase tests (Grimont and Grimont, 1992a).

Richard (1985) recommended the use of brilliant green-bile-lactose-L-tryptophan broth (Diagnostics Pasteur, Marnes-la-Coquette, France) to detect growth, gas production from lactose, and indole production at 44.5°C.

Urease is best tested on the urea-indole medium (Diagnostics Pasteur, Marnes-la-Coquette, France; Richard, 1975). This orange-colored medium is inoculated with a loopful of culture from a sugar-containing medium (e.g., Worfel-Ferguson, Hajna, or Kligler agar). After 30 min to a few h of incubation in a water bath at 37°C, the medium turns purple if urea has been split into ammonium carbonate (Richard, 1975).

Conditions of Incubation

Good results are obtained when *Klebsiella* cultures are incubated at 30–35°C. Although *Klebsiella* isolates from clinical specimens often have an optimal temperature for growth near 37°C, some tests (e.g., Voges-Proskauer test) are more frequently positive at lower temperatures.

Identification of *Klebsiella* at the Genus Level

There is no single test able to separate the present genus *Enterobacter* from the genus *Klebsiella*. *Enterobacter aerogenes* and *E. gergoviae* are metabolically as active as *Klebsiella* species. No strain of *Klebsiella* is motile. However, non-motile strains of *Enterobacter* occur. Adonitol is generally utilized and fermented by *Klebsiella* and not by *Enterobacter* (except *E. aerogenes* and occasionally *E. cloacae*). D-Arabitol is generally utilized by *Klebsiella* and not by *Enterobacter* (except *E. aerogenes*, *E. gergoviae*, and occasionally *E. cloacae* or *E. agglomerans*). D-Sorbose is utilized and fermented by some *Klebsiella* species or strains and never by *Enter-*

obacter species. Urease is produced by *K. pneumoniae*, *K. oxytoca*, *K. planticola* and *K. terrigena* and not produced by all *Enterobacter* species except *E. gergoviae*. The decarboxylase pattern is most useful in identification of the genus *Klebsiella*. All *Klebsiella* species (except *K. mobilis* and *K. pneumoniae* subsp. *rhinoscleromatis* and some strains of subspecies *ozaenae*) produce a lysine decarboxylase (LDC) but no ornithine decarboxylase (ODC; except strains referred to as "*K. ornithinolytica*") or arginine dihydrolase (ADH). *Enterobacter* species either are LDC+, ODC+, and ADH-; or LDC-, ODC+, and ADH+; or LDC-, ODC+, and ADH-; or LDC-, ODC-, and ADH-. Finally, although capsulated *Enterobacter* strains (mostly *E. aerogenes*) occur, the presence of a capsule in a Voges-Proskauer positive, LDC+, ODC-, ADH-, and nonmotile Gram-negative Enterobacteriaceae points the identification toward the genus *Klebsiella*.

The growth of *Klebsiella* on a carbohydrate-rich medium, such as bromothymol blue lactose agar (Ørskov, 1981), Hajna or Kliger medium, or Worfel-Ferguson medium (Edwards and Ewing, 1972) gives a better development of the capsule than a carbohydrate-poor medium.

Worfel-Ferguson Medium (Edwards and Ewing, 1972)

NaCl	2 g
K ₂ SO ₄	1 g
MgSO ₄	0.25 g
Sucrose	20 g
Yeast extract (Difco)	2 g
Agar (Difco)	15 g
Distilled water to	1000 ml

Autoclave at 120°C for 15 min. Use this medium with or without agar. After overnight incubation at 37°C, observe the capsules under the microscope with China ink.

Klebsiella are straight Gram-negative rods, 0.3–1 µm in diameter and 0.6–6 µm in length, often surrounded with a capsule (Ørskov, 1984a). The large mucoid colonies often contain cells with large capsules and those of *K. pneumoniae* subsp. *ozaenae* and *K. pneumoniae* subsp. *rhinoscleromatis* are often voluminous. Usually the methyl red test is negative and the Voges-Proskauer (VP) test is positive, meaning that acetoin and 2,3-butanediol are produced from glucose fermentation and that neutral end products predominate over the acidic end products. Some strains of *K. rhinoscleromatis* do not form acetoin and 2,3-butanediol, other strains produce acetoin and 2,3-butanediol in such small amounts that the methyl red reaction remains positive, and in other strains, the acetoin disappears before the VP reaction is tested, so both tests may be positive or both tests negative (Ørskov, 1984a). Richard's modification of the VP test (Grimont and Grimont, 1992a) gives

most often positive results with *Klebsiella* strains (except *K. pneumoniae* subsp. *ozaenae* and subsp. *rhinoscleromatis*). Esculin is hydrolyzed. Almost all strains in the genus *Klebsiella* (including or not including *K. mobilis*) utilize the following compounds as sole carbon and energy sources (provided growth factor requirements of some strains be met): *N*-acetyl-D-glucosamine, L-alanine, L-arabinose, D-arabitol, L-aspartate, D-cellobiose, citrate, D-fructose, L-fucose, fumarate, D-galactose, gentiobiose, D-gluconate, D-glucosamine, D-glucose, DL-glycerate, glycerol, *myo*-inositol, 2-ketogluconate, DL-lactate, lactose, D-malate, L-malate, maltose, maltotriose, D-mannitol, D-mannose, D-melibiose, 1-*O*-methyl-β-glucoside, L-proline, D-raffinose, D-ribose, L-serine, D-trehalose, and D-xylose (P. A. D. Grimont and E. Ageron, unpublished observations). H₂S, β-glucuronidase, phenylalanine-, and tryptophan deaminase are not produced; DNA and tributyrin are not hydrolyzed; 2,5-diketogluconate is not formed from 2-ketogluconate (Bouvet et al., 1989). Almost no strain of *Klebsiella* (including or not including *K. mobilis*) can utilize the following compounds as sole carbon and energy sources after a 4-day incubation: betaine, caprate, caprylate, glutarate, itaconate, 3-phenylpropionate, and propionate (P. A. D. Grimont and E. Ageron, unpublished observations).

Identification of *Klebsiella* Species

IDENTIFICATION BASED ON PHENOTYPIC METHODS. The phenotypic characteristics that are most useful for the identification of *Klebsiella* species (including *K. mobilis*) are given in Table 1. Results of carbon source utilization tests have been obtained with Biotype-100 strips (BioMérieux, France) together with a minimal medium containing 16 growth factors (Grimont and Grimont, 1992a). The strips were examined for visual growth after two (early reading) and four (late reading) days. These results of carbon source utilization tests are unpublished observations of P. A. D. Grimont and E. Ageron.

Table 1 obviously shows that *K. pneumoniae* subsp. *ozaenae* and *K. pneumoniae* subsp. *rhinoscleromatis* are biotypes of *K. pneumoniae* subsp. *pneumoniae* with less nutritional versatility. There is no substrate utilized by subspecies *ozaenae* and *rhinoscleromatis* that are not utilized by subspecies *pneumoniae*. For this reason, it is safer to check the identification of these less active subspecies by capsular typing (almost all *K. pneumoniae* subsp. *rhinoscleromatis* strains are of serotype K3, whereas *klebsiellae* of serotype K4 are found almost exclusively in *K. pneumoniae* subsp. *ozaenae* and represent the vast majority of strains of this subspecies).

Table 1. Phenotypic characteristics of the *Klebsiella* species and *K. pneumoniae* subspecies.

Symbols and abbreviations: +, 95–100% strains positive in 1–2 days (utilization tests) or in 1 day (other tests); (+), 95–100% strains positive in 1–4 days; –, 95–100% strains negative in 4 days; d, different reactions; ND, no data ONPG, 2-nitrophenyl-β-D-galactopyranoside; and PQQ, pyrroloquinoline quinone.

Oxidation of glucose to gluconate (mediated by glucose dehydrogenase) in the absence of added pyrroloquinoline quinone is a unique property of *K. pneumoniae* subsp. *pneumoniae* among the nonmotile *Klebsiella* (Bouvet et al., 1989). This property is shared by *K. mobilis* (*E. aerogenes*). The other species require the addition of cofactor pyrroloquinoline quinone to express glucose dehydrogenase activity. Gluconate is oxidized to 2-ketogluconate (by a gluconate dehydrogenase) by all nutritionally versatile species except *K. oxytoca*.

Carbon source utilization tests are essential for the precise identification of *Klebsiella* species. Note that *K. oxytoca* is unique in producing a soluble yellow compound in all cupules showing some growth (Grimont et al., 1992b), and this may be the same pigment as that produced by this species on ferric gluconate (Ørskov, 1984a). Growth on *m*-coumarate never occurs with *K. terrigena* and *K. mobilis* (*E. aerogenes*). Growth on gentisate and 3-hydroxybenzoate never occurs with *K. pneumoniae* and *K. planticola*. Growth on histamine never occurs with *K. pneumoniae* and *K. oxytoca*. Growth on D-sorbose is always negative with *K. mobilis* (*E. aerogenes*), and growth on tricarballoylate is always negative with *K. planticola*. Among the *Klebsiella*, only *K. terrigena* and some strains of *K. oxytoca* can grow on D-melezitose, and only *K. planticola* and *K. terrigena* can grow on 3-*O*-methyl-D-glucose. These eight carbon sources are often sufficient for the identification of all *Klebsiella* species (Monnet et al., 1991; Monnet and Freney, 1994). A multicenter evaluation showed that 18 biochemical tests allow identification of all *Klebsiella* species described so far (excluding *K. variicola*, which was not investigated; Hansen et al., 2004).

IDENTIFICATION BASED ON MOLECULAR METHODS. Identification of *Klebsiella* species and phylogenetic groups within *K. pneumoniae* and *K. oxytoca* can now be reliably achieved based on the sequencing of housekeeping genes such as *gyrA* and *parC* (Brisse and Verhoef, 2001) or *rpoB* (Drancourt et al., 2001). A simplified method based on *gyrA* PCR-RFLP was recently developed for species identification (Brisse et al., 2004b). Species can be identified by 16S rRNA gene sequencing, but because of limited nucleotide variation, 16S rRNA sequences cannot be reliably used to distinguish the phylogenetic groups (Brisse and Verhoef, 2001) within *K. pneumoniae* and *K. oxytoca* (S. Brisse, unpublished observation). *Klebsiella* species and phylogenetic groups can be identified using ribotyping (Brisse and Verhoef, 2001) or AFLP (Jonas et al., 2004). *Klebsiella oxytoca* can be differentiated from other *Klebsiella* species by a specific polymerase chain reaction (PCR) assay

targeting the *pehX* gene involved in pectin degradation (Kovtunovych et al., 2003).

Ecology and Epidemiology

Ecological information obtained prior to the recognition of *K. oxytoca*, *K. planticola* or *K. terrigena* is certainly imprecise with respect to the identity of involved species, and mention of environmental isolates of *K. pneumoniae* should often read *Klebsiella* spp.

Klebsiella in Water, Plants and Soil

Klebsiella spp. are often found in a variety of environmental sources such as soil, vegetation and water, contributing to biochemical and geochemical processes, and has been identified as a major component of the microflora in several types of stressed nonclinical environments (Huntley et al., 1976; Vasconcelos and Swartz, 1976; Seidler, 1981; Sjogren and Gibson, 1981; Niemelä et al., 1982). These bacteria have been recovered from aquatic environments receiving industrial wastewaters (Caplenas et al., 1981), plant products, fresh vegetables (Brown and Seidler, 1973), food with a high content of sugars and acids (Duncan and Razzell, 1972; Mundt et al., 1978), frozen orange juice concentrate (Fuentes et al., 1985), sugar cane wastes (Nunez and Colmer, 1968), living trees, plants and plant by-products (Brown and Seidler, 1973; Knittel et al., 1977; Caplenas et al., 1981).

They are commonly associated with wood (Duncan and Razzell, 1972), saw dust, and waters receiving industrial effluents from pulp and paper mills (Duncan and Razzell, 1972; Knittel, 1975; Dufour and Cabelli, 1976; Huntley et al., 1976) and textile finishing plants. As a consequence, the nasal cavities of many workers in paper and board mills proved to be contaminated by *Klebsiella* (Niemelä et al., 1985). *Klebsiella* spp. are also present in drinking water emanating from redwood tanks (Seidler et al., 1977). Isolates have been described several times in forest environments (Knittel et al., 1977; Bagley et al., 1978b), degrading kraft-lignin (Deschamps et al., 1980c), tannic acid (Deschamps et al., 1980b), pine bark (Deschamps and Lebeault, 1980a), and condensed tannins (Deschamps and Lebeault, 1980a; Deschamps and Lebeault, 1981), or from living or decaying wood and bark or composted wood (Deschamps et al., 1979; Deschamps et al., 1983).

Klebsiella strains from industrial effluents and a variety of human and bovine mastitis origins can multiply in pulp waste to levels exceeding 10⁶ cells per ml. *Klebsiella* strains from vegetable surfaces or human infections could grow rapidly

on the surfaces of potatoes and lettuce to numbers exceeding 10^3 organisms per gram of surface peel and leaf after 24 h incubation at room temperature (Knittel et al., 1977).

Klebsiella can frequently be isolated from the root surfaces of various plants (Pedersen, 1978; Haahtela et al., 1981). *Klebsiella pneumoniae*, *K. oxytoca* or *K. planticola* can fix nitrogen and are classified as associative nitrogen fixers, or diazotrophs (Mahl et al., 1965; Ladha et al., 1983). Isolation of nitrogen-fixing *Klebsiella* was reported from rice leaves (Thomas-Bauzon et al., 1982; Ladha et al., 1983), rhizosphere (Rennie, 1982), grassland soil (Line and Loutit, 1971), decaying wood (Seidler et al., 1972), paper mill liquors and effluents (Nielson and Sparell, 1976), and maize stem tissue (Palus et al., 1996). The endophytic lifestyle of two *K. pneumoniae* strains was demonstrated using green-fluorescent protein labeling (Chelius and Triplett, 2000). These strains colonized the intercortical layers of the stem and the maturation region of the root. Association of *K. oxytoca* with barley rhizosphere during an entire vegetative period was demonstrated using a bioluminescence reporter plasmid (Kozyrovska et al., 1994).

Purified type 3 fimbriae, as well as type 1 fimbriae (see the section Properties Relevant to Pathogenicity for Humans in this Volume) of nitrogen-fixing *Klebsiella*, mediate bacterial adhesion to plant roots (Korhonen et al., 1983; Haahtela et al., 1985b). However, type 3 fimbriae are more efficient than type 1 fimbriae in promoting adherence (Haahtela and Korhonen, 1985a). The bacteria adhere strongly to root hairs, and with a markedly lower efficiency, to the surface of the zone of elongation and to the root cap mucilage (Haahtela et al., 1986). No adhesion to the epidermal cell between root hairs was observed (Haahtela et al., 1986).

A number of the *Klebsiella* strains reported from plant material might be *K. planticola* (Bagley et al., 1981). Strains of *K. pneumoniae* sensu stricto, which are associated with plants (e.g., living or decaying wood and bark), differ from those associated with serious human infections. These environmental *K. pneumoniae* strains are most often able to utilize 5-ketogluconate as sole carbon source (P.A.D. Grimont, unpublished observation) and never have capsular types K1 to K6. Strains involved in serious infection do not utilize 5-ketogluconate and may have capsular types K1 to K6, as well as other capsular types. A comparison of three endophytic *K. pneumoniae* strains with two clinical strains (Dong et al., 2003) showed that the plant-associated strains belong to KpIII (Brisse and Verhoef, 2001), whereas the two clinical strains belong to KpI and were not able to colonize the interior of wheat seedlings as efficiently as the

endophytic strains. However, note that KpIII strains may be found in clinical samples from hospitalized patients (Brisse and Verhoef, 2001).

Klebsiella in Animals

Klebsiella spp. can be found in a wide range of mammals (Gordon and FitzGibbon, 1999) and are also present in insects (Dillon et al., 2002) and possibly in many other animal groups. In locusts, *Klebsiella* may contribute, among other bacterial species, to the synthesis of the aggregation pheromone implicated in the change from a grasshopper-like solitary insect to the gregarious form (Dillon et al., 2002). Cockroaches were suggested to play the role of vectors in the hospital environment (Cotton et al., 2000).

Klebsiella pneumoniae is an important cause of metritis in mares. Capsular types K1, K2, and K5 were major causes of epidemic metritis in England, whereas type K7 was associated with sporadic, opportunistic genital infection (Platt et al., 1976). Outbreaks of metritis in mares were due to type K2 in the United States and France (Edwards, 1928; Tainturier and Richard, 1986). The stallion plays an important role in the transmission of *K. pneumoniae*. Type K7 was found on the preputial skin of stallions and may be part of the normal bacterial flora in this location (Platt et al., 1976). Thus it is important to determine the K-type of *Klebsiella* strains isolated from the genital tract of horses to detect stallion carriage of an epidemic strain versus carriage of less pathogenic *K. pneumoniae*.

Klebsiella have been frequently associated with bovine mastitis (Braman et al., 1973) and causes serious infections in other animals including dogs, Rhesus monkeys, guinea pigs, muskrats and birds (Wyand and Hayden, 1973; Fox and Rohovsky, 1975; Kinkler et al., 1976; Wilson, 1994; Roberts et al., 2000). Epidemics of fatal generalized infections among captive squirrel monkeys (*Saimiri sciureus*) in French Guyana and lemurs in a French zoo were due to *K. pneumoniae* K5 and K2, respectively (Richard, 1989). Immunization of the monkeys (or lemurs) with the corresponding capsular polysaccharide was efficient in stopping the epidemic (Postal et al., 1988; Richard, 1989).

Klebsiella in Humans

The interactions of *Klebsiella* with humans range from asymptomatic carriage to opportunistic infections (mainly in hospitalized patients), and also include community-acquired infections. Most *Klebsiella* infections now occur in hospitalized patients and many are caused by antibiotic-resistant strains, including strains that produce extended-spectrum β -lactamases (ESBLs) that

are a serious cause of concern. The importance of klebsiellae as nosocomial pathogens, their epidemiology, and their pathogenicity were reviewed by Podschun and Ullmann (1998a).

Klebsiella pneumoniae was sometimes called “Friedländer’s bacillus” or the agent of Friedländer’s pneumoniae, a community-acquired pulmonary infection that was observed in chronic alcoholics (Carpenter, 1990) and had characteristic radiographic features that were due to severe pyogenic infection. Not all capsular types are associated with acute pneumonia. Type K1 is most frequently isolated in these situations, but K2, K3, K4, K5, and K6 can also be involved (Eickhoff et al., 1966; Ørskov, 1981). Recent data on the prevalence of community-acquired *Klebsiella* pneumonia are not abundant, but Friedländer’s pneumoniae appears to have become rare in the Western world (Vergis et al., 2000). In a multicenter study, Ko et al. (2002) found only four cases of community-acquired bacteremic *K. pneumoniae* pneumonia in hospitals in Europe, the United States, Argentina and Australia, whereas 53 such cases were observed in South Africa and Taiwan. Other reports also indicate that community-acquired *Klebsiella* pulmonary disease is more frequent in South Africa and in Asian countries, where it sometimes ranks first among etiological agents of community-acquired pneumonia (Potgieter and Hammond, 1992; Feldman et al., 1995; Jong et al., 1995; Ishida et al., 1998; Liam et al., 2001).

In humans, carriage is frequent in the intestinal tract and also occurs, albeit less frequently, in the nasopharynx. The number of *Klebsiella* bacteria can attain 10^7 per gram of dry feces (Finegold et al., 1983; Leclerc et al., 2001). *Klebsiella* spp. are found in fecal material from a considerable proportion of persons (Thom, 1970; Montgomerie, 1979; de la Torre et al., 1985; MacFarlane and Narla, 1985). A survey of *Klebsiella* carriage in urban residents (not associated with a hospital environment), hospital personnel, and newly admitted patients showed 30–37% of individuals carry *Klebsiella* (various serotypes), including 29–35% fecal carriage and 3–4% throat carriage (Davis and Matsen, 1974). There was a slight increase in prevalence among long-term patients (43% carriage). Note that about 34% of the strains in this survey were indole-positive (Davis and Matsen, 1974). In general, patient colonization by *Klebsiella* spp. increases with length of stay and antibiotic use (Rose and Schreier, 1968; Pollack et al., 1972; Podschun and Ullmann, 1998a). Health-care workers can also have high rates of *Klebsiella* carriage (Casewell and Talsania, 1979; Cooke et al., 1979). Carriage is considered the major reservoir of *Klebsiella* infections (Selden et al., 1971; Montgomerie, 1979; Podschun and

Ullmann, 1998a). Epidemiological markers (e.g., capsular typing) are necessary to understand the origin of infection (see the section Typing Methods in this Chapter). The endogenous origin of an infection is often claimed because the same capsular type is found in the infected site and in the gut of the patient. This should not mean that no prevention is feasible since the intestinal *Klebsiella* may have been acquired during the hospital stay.

Features predisposing to *K. pneumoniae* or *K. oxytoca* nosocomial infection include extremes of age, chronic alcoholism, diabetes mellitus, chronic cardiac, renal, and pulmonary and neoplastic disease (Feldman et al., 1990; Hansen et al., 1998).

Infections with *Klebsiella* are caused mainly by *K. pneumoniae* and *K. oxytoca* in a proportion estimated at 2 to 1 (Bauernfeind et al., 1981) or 4 to 1 (de la Torre et al., 1985). Most *Klebsiella pneumoniae* infections are caused by strains of phylogenetic group KpI, but groups KpII and KpIII (which corresponds to *K. variicola*) are also found (Brisse et al., 2004b). Infections with *K. planticola* and *K. terrigena* have long been considered exceptional, but this may be due in part to the difficulties of their identification (Monnet et al., 1991; Monnet and Frenay, 1994). In fact, recent reports show that *K. planticola*, and to a lesser extent *K. terrigena*, are not rare in clinical infections (Mori et al., 1989; Podschun and Ullmann, 1992a; Podschun et al., 1998b; Westbrook et al., 2000; Stock and Wiedemann, 2001). *Klebsiella planticola* has been isolated from newborns (Hart, 1993; Podschun et al., 1998b; Westbrook et al., 2000). *Klebsiella planticola* and *K. ornithinolytica* have also been directly involved in histamine fish poisoning (Kanki et al., 2002; see below).

Klebsiellae are widely recognized as important opportunistic pathogens in hospital patients, representing 3–8% of all nosocomial bacterial infections and ranking second (behind *Escherichia coli*) as a cause of nosocomial Gram-negative bacteremia (Podschun and Ullmann, 1998a). They are mostly associated with infections of the urinary and respiratory tracts, as well as wound and soft tissue infections, and can cause fatal septicemia. *Klebsiella* strains have the ability to spread extensively among patients, leading to nosocomial outbreaks, especially in neonatal units (Hart, 1993; Podschun and Ullmann, 1998a). Ørskov (1952) first described clusters of urinary tract infections due to *K. pneumoniae* among hospitalized patients, followed by innumerable numbers of authors who described nosocomial outbreaks of *Klebsiella* strains, especially multiresistant strains (for references, see the section Typing Methods in this Chapter). Plasmids encoding ESBLs carried by *Klebsiella* strains can

also spread to other bacterial strains and species (Coque et al., 2002). Interhospital transmission of *Klebsiella* strains, mostly those producing ESBLs, have been described (Buré, 1988; Arlet et al., 1994; Monnet et al., 1997). Capsular types of *Klebsiella* strains found in hospitals are diverse (Hansen et al., 1998).

In addition to the above-mentioned prevalence of community-acquired *K. pneumoniae* pneumonia in Asia, three severe clinical manifestations have emerged as important public health problems in this part of the world. First, primary bacteremic liver abscess has been described since 1989 in Asia, especially Taiwan (Chang and Chou, 1995; Ko et al., 2002). The Taiwanese patients have no history of hepatobiliary disease, but 70% have diabetes mellitus (Ko et al., 2002). Second, *K. pneumoniae* endophthalmitis, also almost exclusively reported from Asia, may represent a secondary complication of liver abscess (Hidaka et al., 1993; Ko et al. [2002] and references therein). Third, *K. pneumoniae* is the cause of community-acquired bacterial meningitis in adults in Taiwan, even with no association with liver abscess or infections of other body sites. The proportion of cases of culture-proven *K. pneumoniae* bacterial meningitis in one Taiwanese hospital increased from 8% (between 1981 and 1986) to 18% (between 1987 and 1995; Tang et al., 1997; Ko et al., 2002). The genetic basis of these peculiar pathological aspects is so far unknown. The capsular serotypes of blood isolates found in one Taiwan hospital were diverse, although K1 predominated (Cheng et al., 2002). Ribotyping and pulse-field gel electrophoresis (PFGE) also revealed genetic variation among the strains, suggesting that liver abscess is not caused by a single clone. The complication of endophthalmitis, however, may be associated with capsular serotype K1 (Fung et al., 2002).

Recent studies have associated *K. pneumoniae* with chronic diarrhea in HIV-infected persons (Gassama et al., 2001; Nguyen Thi et al., 2003). These seemingly enteropathogenic strains display aggregative adherence to HEp-2 cells, but they do not appear to harbor virulence factors known to be involved in pathogenicity of pathogenic *E. coli* strains (Nguyen Thi et al., 2003).

Klebsiella pneumoniae has been implicated in the development of ankylosing spondylitis because of the high incidence of *Klebsiella* in the bowel flora of patients whose disease is in an active state (Ebringer et al., 1979; Calin, 1984). It is striking that 70–90% of the affected patients share HLA type HLA-B27 (a phenotype present in less than 10% Caucasians). The mimicry between *K. pneumoniae* K43 and human HLA-B27 antigens might be responsible for the development of arthritis (Ogasawara et al., 1986).

Klebsiella pneumoniae subsp. *rhinoscleromatis* is classically associated with rhinoscleroma, a chronic granulomatous disease of the nose. This disease is endemic in Africa, eastern and central Europe, and South and Central America (Ørskov, 1981; Richard, 1982; Hart and Rao, 2000).

Klebsiella pneumoniae subsp. *ozaenae* is considered to be associated with ozena, an atrophic rhinitis with an unpleasant smell (Malowany et al., 1972; Shehata, 1996; Chand and MacArthur, 1997). In the past 10 years, several reports have stated that *K. ozaenae* (now *K. pneumoniae* subsp. *ozaenae*) may cause invasive infections, especially in immunosuppressed hosts: bacteremia with or without meningitis (Berger et al., 1977; Goldstein et al., 1978; Lewis and Alexander, 1979; Murray et al., 1981), otitis, mastoiditis, urinary tract infections, wound infections, corneal ulcers, pneumonia (Berger et al., 1977; Goldstein et al., 1978; Murray et al., 1981; McCarthy and Hubbard, 1984; Janda et al., 1985), or brain abscess (Strampfer et al., 1987). In most of these cases, however, *K. pneumoniae* subsp. *ozaenae* was identified with the sole help of commercial identification kits without confirmation of the identification by capsular typing (see the section Identification in this Chapter).

Klebsiella granulomatis (formerly *Calymmatobacterium granulomatis*) is the presumed causative agent of granuloma inguinale (donovanosis), a genital ulceration that is sexually transmissible. Histologic features include dense dermal infiltrate of plasmacytes, neutrophils and large macrophages with vacuolated cytoplasm that contain intracellular bacilli (Donovan bodies). Carter et al. (1999) pointed out the similarity of donovanosis and rhinoscleroma histologic lesions, which parallels the close genetic relationship of both species to *K. pneumoniae*, but whether the pathogenic properties of these species have a common evolutionary origin is yet unknown.

Properties Relevant to Pathogenicity for Humans

The pathogenicity of *Klebsiella* has been reviewed by Williams and Tomas (1990) and Podschun and Ullmann (1998a). Four components of *Klebsiella* have long been implicated in pathogenesis: adhesins, capsular polysaccharides, lipopolysaccharide (LPS), and iron-scavenging systems (siderophores). Recently, systematic attempts to identify new components involved in colonization and infection have been made using signature-tagged mutagenesis (Maroncle et al., 2002; Struve et al., 2003b), genomic subtractive hybridization (Lai et al., 2000), in vivo expression

technology (Lai et al., 2001), and transposon mutagenesis (Cortes et al., 2002a). Genes possibly involved in *Klebsiella* pathogenesis were identified in these studies, but characterization of their function and role in *Klebsiella* virulence has only just begun (Cortes et al., 2002b; Lai et al., 2003a). Although *K. pneumoniae* is considered an extracellular pathogen, invasion of cultured human epithelial cells from the bladder and ileocecum by *K. pneumoniae* was reported (Fumagalli et al., 1997; Oelschlaeger and Tall, 1997), and it was shown that capsule interferes with adhesion and invasion (Sahly et al., 2000).

Adhesins

Adhesion to mucosal and epithelial cell surfaces is often the first step in the development of colonization and infection. Adhesins are often also hemagglutinins and may be located on fimbriae that protrude on the surface of the bacterial cells. *Klebsiella* fimbriae were studied by Duguid (1959), who demonstrated their association with different hemagglutination (HA) behaviors. Strains of *K. pneumoniae*, *K. oxytoca*, *K. planticola* and *K. terrigena* may produce thick, channelled (type-1) fimbriae, which are closely related to type 1 fimbriae produced by other Enterobacteriaceae species. *Klebsiella* type 1 fimbriae are responsible for D-mannose-sensitive hemagglutination (MS-HA) and cause agglutination of guinea pig erythrocytes. More than 80% of clinical isolates of *K. pneumoniae*, but few *K. oxytoca* strains, express type-1 fimbriae (Przondo-Hessek, 1983; Podschun and Sahly, 1991). Clinical and fecal carriage isolates of *K. pneumoniae* express type 1 fimbriae in higher proportion than environmental strains (Podschun and Sahly, 1991). *Klebsiella mobilis* (*E. aerogenes*) produces antigenically similar fimbriae, which are not associated with hemagglutinin activity. *Klebsiella* type 1 fimbriae are antigenically distinct from those of *Enterobacter* species (Adegbola and Old, 1985). A gene cluster has been found to contain several genes required for the synthesis and assembly of type 1 fimbriae and a 29-kDa protein, the adhesin, located at the tip and at intervals along the fimbria (Purcell et al., 1987; Abraham et al., 1988). At least two forms of the gene, which are antigenically distinct, exist in *K. pneumoniae* (Gerlach et al., 1989a). Type 1 fimbriae mediate the attachment of *K. pneumoniae* to uroepithelial cells and are involved in the development of bladder infection in the rat (Fader et al., 1988; Williams and Thomas, 1990). These fimbriae also mediate adherence to ciliated tracheal cells in vitro (Fader et al., 1988). Although they are believed to be primarily involved in the pathogenesis of lower urinary tract infections, type 1 fimbriae may be involved

in pyelonephritis (Fader and Davis, 1982). The expression of type 1 fimbriae is subjected to phase variation and may be switched off (Fader and Davis, 1982), which is believed to be advantageous to the bacteria in the latter stages of the infection, as these fimbriae can be recognized by leukocytes and trigger the destruction of the bacteria through lectinophagocytosis (Ofek et al., 1995).

Strains of *Klebsiella* also produce thin, non-channelled (type-3) fimbriae that agglutinate ox erythrocytes only when these have been previously treated with tannin, in the absence or presence of D-mannose. This agglutination type has been called "mannose-resistant, *Klebsiella*-like hemagglutination" (MR/K-HA) because it was initially discovered in *Klebsiella* strains, but it is found in many other species (Clegg and Gerlach, 1987). Przondo-Hessek and Pulverer (1983) found that 85% of *Klebsiella* clinical isolates possess the mannose-resistant *Klebsiella* hemagglutinin, mediated by type 3 fimbriae. Podschun and Sahly (1991) found that most strains of *K. pneumoniae* and *K. oxytoca* induced MR/K agglutination. In both species, MR/K agglutination was significantly more frequent in clinical and fecal carriage isolates than in sewage isolates (Podschun and Sahly, 1991).

Type 3 fimbriae can mediate binding to plant roots (Korhonen et al., 1983; Haahtela et al., 1985b), human endothelial cells, epithelia of the respiratory tract, uroepithelial cells, and type V collagen (Tarkkanen et al., 1990; Wurker et al., 1990; Hornick et al., 1992; Tarkkanen et al., 1997). MR/K-HA is inhibited by the polyamine spermidine (Gerlach, 1989b). Spermidine has been suggested to act as a receptor of type 3 fimbriae, as it is present on the surface of damaged erythrocytes but not on untreated ones (Gerlach, 1989b). However, the role of type 3 fimbriae in human infection has not been directly established (Podschun and Ullmann, 1998a).

Type 3 fimbriae are encoded by the *mrk* gene cluster (Allen et al., 1991). The fimbriae are made of a fimbrial shaft composed predominantly of the major subunit MrkA and of the MrkD adhesin that is assembled into the shaft. Functional heterologous fimbriae can be assembled by expressing the *mrkD* gene in a strain containing the *pap* gene cluster (Hornick et al., 1995), suggesting that the assembly apparatus for type 3 fimbriae is related to that of P pili of uropathogenic *E. coli*. In *Klebsiella*, the *mrkD* gene shows variation among hemagglutinating strains (Schurtz et al., 1994). A form of the *mrkD* gene was found on a large native plasmid (Hornick et al., 1995). This form, *mrkD*_{1P}, is frequently found on plasmids among *K. oxytoca* strains, but not among *K. pneumoniae* strains, which have a distinct chromosomal gene,

*mrkD*_{1C}. The other *mrk* genes of the cluster are more conserved, regardless of whether they are present on a chromosome or a plasmid (Hornick et al., 1991; Hornick et al., 1995). Type V collagen-binding specificity is a function of the MrkD_{1P} protein (Tarkkanen et al., 1990; Hornick et al., 1995), whereas the presence of MrkD_{1C} is associated with the ability to bind both type IV and type V collagen. However, some hemagglutinating strains possessing a gene related to *MrkD*_{1C} do not bind to either type IV or type V collagen (Sebghati et al., 1998). Mutations impairing either assembly into the fimbrial shaft or binding to type V collagen were identified (Sebghati and Clegg, 1999).

Type 3 fimbriae could be responsible for colonization of the surfaces of indwelling devices, as they are involved in adherence to abiotic surfaces and biofilm formation (Langstraat et al., 2001; Di Martino et al., 2003). Biofilm formation appears to be mediated by the fimbrial shaft protein MrkA and not by the adhesin (Langstraat et al., 2001).

Other adhesins have been described in *Klebsiella*. In a search for bacterial factors responsible for the adhesion of *K. pneumoniae* to intestinal cells, Darfeuille-Michaud et al. (1992) found a nonfimbrial adhesin of 29 kDa that was designated "CF29K." Its gene was encoded on a large conjugative plasmid, which also contained genes for broad-spectrum cephalosporin resistance and aerobactin (Darfeuille-Michaud et al., 1992). A novel fimbrial adhesin termed "KPF-28" was found (Di Martino et al., 1996) as a long, thin, and flexible fimbria 4–5 nm in diameter and 0.5–2 µm long. It is involved in the adherence to the human carcinoma cell line Caco-2. As for CF29K, this adhesin was also encoded on a plasmid, and it was associated to strains producing SHV-4 extended-spectrum β-lactamase. ("SHV" is a contraction of "sulfhydryl variable": a description of the biochemical properties of this β-lactamase.)

The role of the capsular polysaccharide in promoting or impairing adhesion to epithelial cells and mucosal surfaces has been recently re-evaluated. While capsular polysaccharide may enhance adhesion to mucus-producing cells and appears necessary for colonization of large intestines of streptomycin-treated mice (Favre-Bonte et al., 1999a; Favre-Bonte et al., 1999b), it impedes the adhesion to epithelial cells (Favre-Bonte et al., 1999a; Sahly et al., 2000; Struve and Krogfelt, 2003a). Capsular-like material has also been suspected to be responsible for aggregative adherence to human intestine-407 cells (Favre-Bonte et al., 1995). The capsule may interfere with the expression of adhesins, perhaps at the transcriptional level (Favre-Bonte et al., 1999a; Sahly et al., 2000).

Capsular Polysaccharides

Klebsiella strains are surrounded by a generally thick hydrophilic polysaccharide capsule responsible for the glistening, mucoid aspect of colonies on agar plates. A total of 77 antigenically distinct exopolysaccharides have been recognized so far and are included in the international K-serotyping scheme (Ørskov and Fife-Asbury, 1977). The chemical structure of most K-antigen types has been analyzed (Ørskov and Ørskov, 1984b). Capsular polysaccharides are acidic and composed of repeats of basic units of four to six sugars. It has been shown that noncarbohydrate groups are also present on some capsular types, but very little is known about the immunochemical specificity of *Klebsiella* capsular polysaccharides.

The capsule was the first virulence factor described for *Klebsiella* (Toenniesen, 1914; Baerthlein, 1918; Kauffmann, 1949; Mizuta et al., 1983; Williams et al., 1983; Cryz et al., 1984a). In 1928, Edwards showed that capsule production by *Klebsiella* was necessary to produce metritis in mares (Edwards, 1928). A relationship was found between the size of capsule (capsular types 1 and 2) and pathogenicity in diverse experimental models (Domenico, 1982; Cryz et al., 1984a). Pollack (1976) demonstrated detectable levels of circulating capsular polysaccharide in patients infected by *K. pneumoniae* and suggested a correlation between antigenemia and severity of infection. The increased virulence conferred by the capsular material has been explained on the basis of protection against phagocytosis by polymorphonuclear leukocytes (Simoons-Smit, 1984; Podschun et al., 1992; Podschun and Ullmann, 1992b) and against killing by serum (Williams et al., 1983; Simoons-Smit et al., 1986). The K-antigen plays a crucial role in protecting the bacterium from opsonophagocytosis in the absence of specific antibodies, by blocking complement deposition or activation (Williams et al., 1983; Simoons-Smit et al., 1986; Williams et al., 1986; Williams and Thomas, 1990). Capsular polysaccharide was also shown to be essential to *K. pneumoniae* virulence in a murine model of pneumonia (Cortes et al., 2002a). In this model, the capsule modulates C3 deposition and protects the bacteria against alveolar macrophage phagocytosis.

Differences in virulence between *Klebsiella* capsular serotypes have long been recognized (Kauffmann, 1949). On the basis of mouse lethality, Mizuta et al. (1983) showed that serotypes K1 and K2 were the most virulent *Klebsiella* serotypes when injected intraperitoneally. However, the finding of avirulent strains belonging to the O1:K2 serogroup that were fully encapsulated, suggested that factors other than

the cell-associated capsular material could play a role in virulence. Simoons-Smit et al. (1984) examined the virulence of clinical isolates of *Klebsiella* in a mouse-skin model and showed that strains with K1, K2, K4, and K5 capsular antigens were more virulent for mice than strains with K6 and K above 6. Note, however, that not all K serotypes have been tested in these studies.

The mannose content of the capsular polysaccharide may determine the degree of virulence associated with a given K serotype. Capsular polysaccharides of low-virulence serotypes, such as K7 and K21a (Podschun et al., 1992c; Ofek et al., 1993), have specific mannose-containing structures and are recognized by a lectin on the surface of the macrophages. Through the phenomenon termed "lectinophagocytosis" (Athamna et al., 1991), macrophages ingest and kill the bacteria harboring these structures. In contrast, K2 polysaccharides, which do contain mannose but in a different configuration, are not recognized by macrophages (Ofek et al., 1993; Kabha et al., 1995). In elegant experiments of genetic exchange of the capsular polysaccharide gene clusters between a K2 strain and a K21a strain, Ofek et al. (1993) showed that the recipient strain expressing heterologous *cps* genes exhibited the macrophage-binding phenotype of the donor. In another study, this group reported that surfactant protein A, the main protein component of lung surfactant, enhances the phagocytosis by alveolar macrophages of *Klebsiella* K21a strains but not of K2 strains, a reaction that was inhibited by mannan (Kabha et al., 1997). Zamze et al. (2002) found that the macrophage mannose receptor did not bind to the capsular polysaccharides of a number of *Klebsiella* K-types. In this study, no direct correlation was found between the structure of the polysaccharide and binding to the mannose receptor, suggesting that conformation, rather than sugar content, may be important. However, serotypes K2, K7 and K21 were not tested in this study (Zamze et al., 2002).

Studies of the distribution of K-serotypes among *Klebsiella* clinical isolates showed very distinct prevalence patterns of K-types across distinct geographic regions (Richard, 1973; Rennie and Duncan, 1974; Blanchette and Rubin, 1980; Simoons-Smit et al., 1985; Cryz et al., 1986; Toivanen et al., 1999; Fung et al., 2000). For example, serotype K1 is frequently isolated in studies from Taiwan, China and Japan but is absent from most seroepidemiology studies in Europe and the United States. K2 and K21 appear to be the only frequently found serotypes in most studies (Fung et al., 2000), but other studies reported very few K2 strains (Rennie and Duncan, 1974; Simoons-Smit et al., 1985). The reasons for these differences are not understood and may include

geographic differences, temporal shifts linked to antibiotic usage or other selective pressures, and inconsistent identification of *Klebsiella* species combined with distinct prevalence of K-types among species. However, knowledge of the prevalence of K-types is relevant to vaccine development (Cryz et al., 1985) or humoral immunotherapy (Donta et al., 1996; Lepper et al., 2003) based on capsular polysaccharides.

The genomic organization of the chromosomal region that is responsible for capsular polysaccharide synthesis in a K2 *K. pneumoniae* strain was determined by Arakawa et al. (1995). Nineteen possible open reading frames (ORFs) were identified in the 24,329-bp nucleotide sequence of the *cps* region. Most of them appear to be organized into two transcriptional units. Among these ORFs, the *gnd* gene coding for 6-phosphogluconate dehydrogenase was identified downstream of the longest transcriptional unit. This gene separates the bulk of *cps* genes from two genes responsible for the synthesis of the mannose residue that is part of the K2 polysaccharide unit (Arakawa et al., 1995). The genomic organization of the *cps* region has not been described for other *Klebsiella* K antigens. Rahn et al. (1999) have pointed out the conservation of the genetic organization of the *cps* gene cluster between some *Klebsiella* serotypes and some *E. coli* group 1 K antigens. *Escherichia coli* K30 and *Klebsiella* K20 antigens have a high degree of similarity in gene organization and nucleotide sequence. In these strains, the sequence upstream of the *cps* cluster shows the presence of insertion sequence (IS) elements, which may have been responsible for the horizontal transfer of the *cps* locus between these species (Rahn et al., 1999).

Some encapsulated *K. pneumoniae* isolates form glistening mucoid colonies of viscid consistency. Loss of this phenotype in subcultures was associated with a reduction of virulence (Takahashi et al., 1977). This mucoid phenotype was earlier considered to be the result of overproduction of capsular polysaccharide (Takahashi et al., 1977). Nassif et al. demonstrated that the mucoid phenotype is determined by a gene, designated "*rmpA*" (for regulator of mucoid phenotype), located on a 180-kb plasmid, which also carries the aerobactin gene (Nassif et al., 1989a; Nassif et al., 1989b). A mutation in *rmpA* increases the 50% lethal dose for mice by 1000-fold, although the mutated strain still expresses its capsular specificity. When this gene is introduced in *E. coli*, it triggers the production of colanic acid. Hypothetically, *rmpA* is a regulatory gene which controls the production of a shield (of unknown composition) surrounding the bacteria and protecting them from interaction with anticapsule-specific antibodies

(Nassif et al., 1989a; Nassif et al., 1989b). Similar findings were reported by Wacharotayankun et al. (1993) from another K2 *K. pneumoniae* strain, CG43, in which the about 200-kb plasmid was called “pLVKP” (for large virulence plasmid of *Klebsiella*), and the gene that enhances the mucoidy of colonies was called “*rmpA2*.” RmpA2 was shown to function as a trans-acting regulator for the capsule synthesis (Arakawa et al., 1991; Wacharotayankun et al., 1992) and to regulate K2 capsule expression at the transcriptional level (Lai et al., 2003b). Note that the two-component regulatory system genes, *rscA* and *rscB* (for regulator of capsule synthesis), have been cloned from *K. pneumoniae* and shown to activate colanic acid production when expressed in *E. coli* (Allen et al., 1987; McCallum and Whitfield, 1991). Therefore, it is believed that RmpA (or RmpA2) increases capsule production above that normally achieved by Rcs activation alone (Rahn and Whitfield, 2003).

Lipopolysaccharide

The lipopolysaccharide (LPS) molecule is composed of lipid A, a core polysaccharide and a side chain called the “O-antigen.” Nine O-antigen types are distinguished in *K. pneumoniae*, O1 being the most frequent (Hansen et al., 1999). The most important role of the O-antigen is to protect *K. pneumoniae* from complement-mediated killing, as capsulate or non-capsulate strains lacking the O1 antigen are very sensitive to the bactericidal action of both the alternative and classical complement pathways (Williams et al., 1983; Tomas et al., 1986; McCallum et al., 1989; Williams and Thomas, 1990). For this protection, O-antigen chain length seems to be important (Ciurana and Tomas, 1987; McCallum et al., 1989). C3b is readily deposited on the surface of K⁻ O⁺ cells, but the membrane attack complex fails to kill the cells, possibly due to a steric effect of the long O chain (Williams and Thomas, 1990). Nevertheless, the O-antigen is extremely efficient at activating the early components of the complement, and opsonization renders K⁻ O⁺ bacteria susceptible to phagocytosis in nonimmune serum (Williams and Thomas, 1990). These results have been obtained for the O1 antigen, and it is unclear whether they can be extended to other O-types. However, using well-characterized isogenic mutants, Merino et al. (2000) showed that the O5-antigen LPS is also essential for serum resistance and is an important factor for the adhesion to uroepithelial cells, possibly because of its surface charge and hydrophobicity properties. In contrast, Cortes et al. (2002a) showed that the LPS plays no major role in the establishment of *K. pneumoniae* pneumonia in a murine model.

The O1 lipopolysaccharide has been linked with the extensive tissue necrosis that complicates *Klebsiella* infections (Straus et al., 1985). The production of an extracellular toxic complex (ETC) that has been shown to be responsible in mice for lethality and extensive lung necrosis is composed of 63% capsular polysaccharide, 30% lipopolysaccharide, and 7% protein (Straus, 1987). Antibodies produced against the lipopolysaccharide portion (possessing the toxicity) of the ETC have been shown to be protective (Straus, 1987).

The cluster of genes responsible for the synthesis of the core lipopolysaccharide of *K. pneumoniae* has been genetically characterized (Noah et al., 2001; Regue et al., 2001). Disruption of one of the ORFs, *orf10*, resulted in a two-log-fold reduction of virulence in mice, as well as in a strong reduction in the capsule amount (Regue et al., 2001). A monoclonal antibody that is specific for the genus *Klebsiella* was identified that binds to a conserved epitope of the core region (Brade et al., 2001).

Siderophores

Iron is essential for bacterial growth. Brewer et al. (1982) observed that virulence was enhanced by hyperferremia, suggesting that iron scavenging may also be a virulence factor. In the human body, iron is complexed to carrier molecules such as transferrin (in the serum) or lactoferrin (in milk and other secretions), or sequestered within cells (in heme proteins). Under conditions of iron limitation, potentially pathogenic Enterobacteriaceae produce high-affinity systems (siderophores) to solubilize and import the required iron. The iron-chelating compounds produced are mostly of two sorts, phenolates (e.g., enterochelin) and hydroxamates (aerobactin; Payne, 1988). In response to iron deprivation, *K. pneumoniae* strains were found to induce between four and six iron-repressible outer-membrane proteins in the 70–85 kDa range. All strains were found to produce enterochelin, while only a few could produce aerobactin (Williams et al., 1987). Krone et al. (1985) showed that *K. pneumoniae* strains belonging to serotype K2 harbor a large conjugative plasmid that encodes production of aerobactin and a 76-kDa outer membrane protein. Nassif and Sansonetti (1986) correlated the virulence of *K. pneumoniae* serotypes K1 or K2 with the presence of a 180-kb plasmid encoding the hydroxamate siderophore aerobactin (in addition to gene *rmpA*, see above). The introduction of the aerobactin genes within an avirulent plasmidless recipient enhanced the virulence by 100-fold, but virulence did not reach the level of the wild-type strain. These results suggested that aerobactin is an essential factor of pathogenicity

(Nassif, 1986). Some strains of *K. pneumoniae* express a ferric aerobactin uptake system without making the chelator itself. This may confer a selective advantage in mixed infections in competition with other aerobactin-producing bacteria (Williams and Thomas, 1990). A third siderophore called “yersiniabactin,” which is encoded by the *Yersinia* high-pathogenicity island, was shown to be present in *Klebsiella* (Bach et al., 2000; Koczura and Kaznowski, 2003), but its prevalence in *Klebsiella* species and its role in *Klebsiella* pathogenesis are unknown.

Other Factors

Little is known about the hemolysins produced by *Klebsiella* that were considered as non-hemolytic for human red blood cells (Smith and Ngui-Yen, 1980) and found to be hemolytic in rabbit blood agar (Albesa et al., 1980). Two hemolysins active on rabbit red blood cells were purified by Albesa et al. (1985), who gave the first description of a thiol-activated hemolysin in Gram-negative bacteria. Camprubi et al. (1990) reported that a high level of hemolysin production and excretion could be influenced by the presence of lipopolysaccharide.

Other potential virulence factors produced by *K. pneumoniae* possibly include the production of heat-labile and heat-stable endotoxins (Wadstrom et al., 1976; Klipstein et al., 1983). Recent factors undergoing evaluation for a role in pathogenesis include the two-component system KvgAS (Lai et al., 2003a), HtrA (which may be involved in serum complement resistance; Cortes et al., 2002b), a protein-tyrosine kinase, and a phosphotyrosine-protein phosphatase (the last two being involved in the synthesis of capsular polysaccharide; Preneta et al., 2002).

Human Vaccine

An alternative to the use of antibiotics is to attempt immunological control of *Klebsiella* infections, either by vaccination of patients at risk or by immunotherapy. Anti-capsular polysaccharide antibodies were found to provide a high degree of protection against corresponding capsular serotypes (Cryz et al., 1984b; Cryz et al., 1985). A 24-valent *Klebsiella* capsular polysaccharide vaccine has been prepared by Cryz et al. (1985). Phase I trials indicated that the vaccine was safe (Edelman et al., 1994). A good antibody response was observed with this vaccine in patient victims of acute trauma, with nine out of ten patients responding to at least 18 of the 24 antigens (Campbell et al., 1996). The 24-valent vaccine was used to immunize 2000 healthy volunteers (simultaneously with a *Pseudomonas* vaccine) to obtain a hyperimmune

intravenous immunoglobulin preparation, which was tested in a randomized clinical trial in intensive care unit patients (Donta et al., 1996). The incidence and severity of infections caused by *Klebsiella* strains with K-types included in the vaccine was not affected by the immunization. It was later found that the hyperimmune immunoglobulin persisted longer than expected in the serum, which may be of interest from a clinical point of view, but difficult to explain (McClain et al., 2001). A problem faced by anticapsular vaccination is the variability of capsular antigens in the natural *Klebsiella* populations. The selection of vaccine serotypes in the 24-valent vaccine was based on the most prevalent serotypes from bacteremic infections in Europe and the United States (Cryz et al., 1986). However, the serotypes included in this vaccine represent only 29% of the strains found in Taiwan (Fung et al., 2000) and do not include serotype K1, which is frequent in Asia. The polyvalent vaccine is likely to protect against *E. aerogenes* (Cryz et al., 1990) because of immunological crossreactions.

Vaccination against the *Klebsiella* O-antigen variation is attractive for several reasons. First, it is much less variable than the K-antigen, with only nine distinct serotypes (Fujita and Matsubara, 1984; Trautmann et al., 1996; Hansen et al., 1999) and with serotype O1 representing a large fraction of the isolates (e.g., nearly 40% of the isolates in the study of Trautmann et al., 1997). Second, in spite of the presence of the thick capsule, the O-antigens are exposed to the surface (Tomas et al., 1991), and anti-O1 monoclonal antibodies were shown to be protective in experimental models (Mandine et al., 1990; Rukavina et al., 1997).

Other candidate vaccines against *Klebsiella* infection or its pathogenic effects include a cytotoxin toxoid (Singh and Sharma, 2001), a conjugate made of O-polysaccharide and iron-regulated cell surface proteins (Chhibber and Bajaj, 1995), and hepta- or monovalent bacterial lysates (Kuenen et al., 1994).

The *Klebsiella* outer membrane protein A (KpOmpA) was shown to have properties of a carrier protein when conjugated to *Streptococcus pneumoniae* polysaccharides (Libon et al., 2002) and is suitable for nasal immunization (Goetsch et al., 2001). KpOmpA interacts with antigen-presenting cells by activating them, triggering cytokine production by macrophages and dendritic cells (Jeannin et al., 2002).

Antibiotic Susceptibility

In the last decades, the levels of antibiotic resistance of *Klebsiella* strains involved in nosocomial infections has been changing rapidly for many antimicrobial classes and compounds, in particu-

lar for the successive generations of β -lactam antibiotics. For figures on the prevalence of antimicrobial resistance in different clinical settings and infection types, the reader is referred to recent publications (Livermore, 1995; Bauernfeind, 1996; Brisse et al., 2000; Paterson et al., 2000; Jones, 2001; Paterson, 2001; Stock and Wiedemann, 2001; Bouza and Cercenado, 2002; Gupta, 2002; Paterson, 2002; Paterson et al., 2003).

Strains of *Klebsiella* are naturally resistant to aminopenicillins (ampicillin and amoxicillin) and carboxypenicillins (carbenicillin and ticarcillin) and other penicillins but susceptible to most other β -lactam antibiotics. This natural resistance is due to the low-level constitutive production of a chromosomal class A β -lactamase, which is inhibited by clavulanic acid. Narrow-spectrum cephalosporins (cephalotin and cephalixin) can also be inactivated, although their minimum inhibitory concentrations (MICs) are low (Livermore, 1995). The chromosomal β -lactamase genes are known as *bla_{SHV}* and *bla_{LEN}* in *K. pneumoniae* (Arakawa et al., 1986; Hæggman et al., 1997; Chaves et al., 2001) and *bla_{OXY}* in *K. oxytoca* (Arakawa et al., 1989; Fournier et al., 1996). In *K. pneumoniae*, *bla_{SHV}* is found in strains of phylogenetic group KpI (Brisse and Verhoef, 2001), whereas *bla_{LEN}* is the chromosomal gene of KpIII strains (Hæggman et al., 2004). KpII strains harbor a new variant of the gene named "*bla_{OKP}*" (Hæggman et al., 2004). At least three groups of *bla_{OXY}* β -lactamase genes can be distinguished (Fournier et al., 1996; Granier et al., 2003a; Granier et al., 2003b). In *K. oxytoca*, the chromosomal β -lactamase can be overexpressed, leading to a characteristic antibiogram showing a high resistance to all the penicillins except temocillin, resistance to cefuroxime, aztreonam, cefotaxime and ceftriaxone, but susceptibility (in contrast to isolates producing ESBL enzymes) to ceftazidime. Overexpression has been attributed to mutations in the promoter sequences of the *bla_{OXY}* β -lactamase genes (Fournier et al., 1995). Because of the very high amounts of enzyme expressed, hyperproducers are often resistant to the presence of β -lactamase inhibitors (Livermore, 1995). Hyperexpression of chromosomal *bla_{OXY}* genes has been found in 10–20% of *K. oxytoca* European clinical isolates (Liu et al., 1992; Reig et al., 1993; Livermore and Yuan, 1996).

In *K. pneumoniae*, higher levels and wider spectra of resistance to β -lactams mostly result from the production of plasmid-mediated β -lactamases, often SHV1 and its ESBL derivatives. The strains producing SHV1 remain susceptible to third generation cephalosporins (e.g., cefotaxime). Since 1983 (Knothe et al., 1983), the emergence of resistance of *K. pneumoniae* and

K. oxytoca isolates to third-generation cephalosporins (cefotaxime and ceftazidime) and aztreonam has been reported with increasing frequency (Kliebe et al., 1985; Buré et al., 1988; Jarlier et al., 1988; Gutmann et al., 1989; Podbielski et al., 1991; Paterson et al., 2003). Resistance is most often mediated by plasmids with various alterations of the SHV1, TEM1 and TEM2 β -lactamases (Barthélémy et al., 1988). (The name "TEM" is a contraction of Temoniera, the name of a patient from whom the first resistant bacteria known to contain TEM β -lactamases were isolated.) More than 50 amino-acid sequence variants of SHV and more than 120 variants of TEM have been described and are compiled on the Internet on the Lahey Clinic Web site (<http://www.lahey.org>). At least 50 such variants have been described in *K. pneumoniae* (Bouza and Cercenado, 2002). The evolution of β -lactamase resistance and corresponding β -lactamases have been the subject of several excellent recent reviews (Livermore, 1995; Heritage et al., 1999; Tzouveleakis and Bonomo, 1999; Bradford, 2001; Helfand and Bonomo, 2003), to which we refer the interested readers.

ESBLs are most commonly found in *K. pneumoniae*. A surveillance study in the United States indicated increased MICs (2 μ g/ml or more) of ceftazidime for 24% of *K. pneumoniae* and 15% *E. coli* isolates (Jones et al., 1998). In a recent multicenter survey, phenotypic evidence for ESBL production was found in 73 (16%) out of 455 bloodstream isolates collected in the years 1996–1997 (Paterson et al., 2003), most isolates showing evidence for production of more than one β -lactamase (mean 2.7, range 1–5). The most common ESBL was SHV (in 49 of the 73 producers), whereas TEM was found in 12 ESBL producers, and CTX-M type ESBLs in 17 ESBL producers. These latter ESBL types, which are much more active against cefotaxime than against ceftazidime, pose a problem of detection, as screening procedures for ESBL production often rely on ceftazidime resistance.

New β -lactam resistance phenotypes of concern that have been described in *Klebsiella* include carbapenem-hydrolyzing enzymes (Bradford et al., 1997; Ahmad et al., 1999; Livermore and Woodford, 2000; Yigit et al., 2001), including one produced by a variant of the chromosomally-encoded *bla_{SHV1}* gene (Poirel et al., 2003), and plasmid-mediated *ampC* β -lactamases, which are generally resistant to β -lactamase inhibitors (Bradford et al., 1997; Rupp and Fey, 2003). However, at present carbapenems are very active in vitro against the vast majority of *Klebsiella* strains.

Klebsiella isolates remain generally susceptible to quinolones, trimethoprim-sulfamethoxazole, and aminoglycosides (Watanabe et al., 1980;

Stock and Wiedemann, 2001; Bouza and Cercenado, 2002). However, plasmids mediating aminoglycoside-modifying enzymes have spread in the last three decades and are often carrying ESBL genes as well (Fernandez-Rodriguez et al., 1992; Paterson 2001; Sarno et al., 2002). An association between ESBL production and quinolone resistance has also been described (Brisse et al., 2000; Paterson et al., 2000). Quinolone resistance is generally determined by mutations in the chromosomal genes *gyrA* and *parC* (Deguchi et al., 1997; Brisse et al., 1999) but can also be encoded on plasmids (Martinez-Martinez et al., 1998).

Genomics

The genome of one *K. pneumoniae* strain, MGH 78578, which belongs to *K. pneumoniae* phylogenetic group KpI, has been partially sequenced by the Washington University Genome Sequencing Center (McClelland et al., 2000). A whole genome shotgun approach was used to generate an approximately 8x coverage. The genome sequence is not annotated yet, but BLAST searches can be performed (at the <http://www.genome.wustl.edu/blast/client.pl> {Genome Sequencing Center of Washington University in St. Louis Web site}). Comparison of a 3.9x coverage of the *K. pneumoniae* genome with the sequenced *E. coli* K12 genome identified 2423 common genes with an average of 82% nucleotide similarity (McClelland et al., 2000). Genes common to *E. coli* K12 and *K. pneumoniae* but absent in the three *S. enterica* serovars Typhi, Typhimurium, and Paratyphi A, were found.

The genes common to *E. coli* K12 and the *K. pneumoniae* maize endophyte strain 342, which belongs to phylogenetic group KpIII (Dong et al., 2003), were investigated by hybridization on a microarray containing 96% of the annotated ORFs of *E. coli* K12 (Dong et al., 2001). Three thousand genes were found to be common between the two organisms, using a threshold of 55% nucleotide similarity, whereas 1030 *E. coli* genes were absent in strain 342. This approach, however, does not reveal the genes of *K. pneumoniae* that are not present in *E. coli*. The results were congruent with the known physiological characteristics of the two strains. For example, strain 342 lacks a homolog of the *E. coli* tryptophanase gene responsible for indole formation from tryptophan, and genes necessary for flagellum biosynthesis and function are missing in the *K. pneumoniae* strain 342 (Dong et al., 2001).

Typing Methods

Klebsiella species are genetically heterogeneous and strains within species and subspecies can be discriminated by a number of methods including

biochemical tests, analysis of antigenic specificities, bacteriophage susceptibility typing, bacteriocin susceptibility or production typing, and molecular typing methods.

BIOTYPING Several tests, giving different reactions within a collection of *K. pneumoniae* strains, have been used empirically to biotype *K. pneumoniae* and other *Klebsiella* species. Although much less powerful than the other typing methods, biotyping can be performed in many laboratories and can provide ecologically meaningful information. However, nowadays, biotyping is not commonly used for typing.

The fermentation of dulcitol, D-tartrate, citrate and mucate, urea splitting, and the Voges-Proskauer test have been proposed for biotyping by Kauffmann (1949). Ørskov (1957) found 26 biotypes among 125 indole- and gelatin-negative strains belonging to 68 K-antigen types based on the dulcitol, adonitol, sorbose, urease, D-tartrate and sodium citrate tests; and 10 different biotypes among 50 indole- and gelatin-positive strains of 29 capsule types. Duncan and Razzell (1972) found 29 distinct biotypes using indole, Voges-Proskauer; lactose, sucrose and dulcitol fermentation; malonate, citrate, and D-gluconate utilization; lysine and ornithine decarboxylase; and urea hydrolysis tests in agar media inoculated with a modified Steers replicator. Barr (1978) observed large variation in the metabolism of most substrates examined, and his biotyping system used different concentrations of carbohydrate substrates, and citrate, malonate and urea tests. A biotyping system has been used by C. Richard at the Institut Pasteur (Richard, 1973; Richard, 1982). The tests included sorbose, dulcitol, L-tartrate fermentation, and secondarily rhamnose and adonitol fermentation. For biotype determination in *K. pneumoniae* subsp. *pneumoniae*, mucate, malonate utilization, and urea hydrolysis, or growth at 44°C were found useful (Richard, 1985). For typing *K. oxytoca*, D-melezitose fermentation, tetrathionate reductase activity, brown pigment production on a mineral gluconate-ferric citrate medium were found useful (Richard and Monteil, 1987). A biotyping method based on carbon source utilization tests is under development for *K. pneumoniae*. Among the selected tests, utilization of 5-ketogluconate could discriminate between plant-associated strains (utilization positive) and clinical strains (no utilization; P. A. D. Grimont and E. Ageron, unpublished observation). Finally, a method based on the measurement of the kinetics of 32 metabolic reactions performed in microtiter plates has been developed and is commercially available (Tullus et al., 1999).

Biotyping has a potential value in epidemiological studies when used in conjunction with

capsular serotyping. Use of the two methods together allows the recognition of many more types than is possible with only one of the methods (Rennie and Duncan, 1974).

SEROTYPING Serotyping of *Klebsiella* strains, which are nonmotile, is based on the characterization of the O- and K-antigens.

O-serotyping has long been technically difficult to perform because the presence of heat-stable K-antigens makes determination of O-antigens difficult (Ørskov and Ørskov, 1984b). One way around this problem is to generate non-capsulated variants by subculturing in a nutrient broth containing 50% bile. Because only nine O-antigens have been described (Fujita and Matsubara, 1984; Trautmann et al., 1996; Hansen et al., 1999), O-typing is considered less useful than K-typing for molecular epidemiology and outbreak investigation. However, the increasing levels of antimicrobial resistance in *Klebsiella* strains have renewed interest in O-antigens as potential vaccines (see the section Human Vaccine in this Volume). In addition, O-typing can subdivide K-types, and the development of a modified enzyme-linked immunosorbent assay (ELISA) for O-antigen determination (Alberti et al., 1993; Trautmann et al., 1996) has rendered O-typing easier to perform.

Capsule serotyping or K-typing is presently one of the preferred methods for typing *Klebsiella* strains, as it is highly discriminatory and the only definitive typing method available (Hansen et al., 2002). Unfortunately, this technique is only available in reference centers. An alternative to serotyping that targets the genetic region involved in capsular polysaccharide synthesis was developed recently (Brisse et al., 2004a).

Following the pioneering work of Julianelle (1926), who described the first two capsular serotypes, a total of 82 K-antigens (K1–K82) were described. After deletion of five antigens (K73 and K75–K78), 77 K-antigens are now included in the international K-typing scheme (Ørskov and Fife-Asbury, 1977; Ørskov and Ørskov, 1984b). Antisera used for *Klebsiella* capsular typing can also type *E. aerogenes* (Richard, 1977).

The majority of K-antigens contain only a charged monosaccharide constituent, most often glucuronic acid and hexoses. However, noncarbohydrate constituents (such as formyl or acetyl group and ketal-linked pyruvate) are found: these may function as antigenic determinants and be the cause of crossreactions of some polysaccharides (Edmonston and Cooke, 1979b; Ørskov and Ørskov, 1984b; Ewing, 1986). Crossreactions between K-antigens are numerous and it is necessary in several cases to absorb the antisera for diagnostic use.

Several typing procedures may be used: 1) The capsular swelling reaction or Quellung reaction (Kauffmann, 1949; Edwards and Ewing, 1972; Richard, 1973; Ørskov and Ørskov, 1984b) is the most often used. Cultures on carbohydrate-rich media (e.g., Worfel-Ferguson medium) yield thicker capsules. The test is performed by mixing equal volumes of the bacterial suspension (1×10^8 colony-forming units per ml) and the antiserum (pooled-, specific-, or absorbed antiserum) on a glass slide. After application of a coverslip, the preparation is examined under the ordinary light microscope or the phase-contrast microscope using an oil immersion objective. The capsule-antibody precipitate becomes refractile and visible under the microscope. 2) In the indirect immunofluorescence test, bacteria are incubated with a capsular antiserum (from rabbit), then incubated with a sheep anti-rabbit fluorescent conjugate, and examined under a fluorescence microscope (Riser et al., 1976a; Riser et al., 1976b). 3) A double diffusion gel precipitation (Ouchterlony) test used with carefully absorbed sera has been found to give straightforward results (Mori et al., 1989). 4) A countercurrent immunoelectrophoresis technique was reported to be more specific, more economical, and less time-consuming than the capsular swelling method (Palfreyman, 1978). It is currently in use at the World Health Organization Collaborative Center on *E. coli* and *Klebsiella* (Hansen et al., 2002). 5) The antibody-coated *Staphylococcus* coagglutination test (Onokodi and Wauters, 1981) uses *Staphylococcus* Cowan I, which contains large amounts of protein A on its surface. Protein A binds antisera, and the suspension of staphylococcal cells coated with specific antisera becomes a reagent for specific coagglutination with corresponding *Klebsiella*. And finally, 6) the latex agglutination test is an alternative method in which latex particles are used in place of *Staphylococcus* Cowan I (Onokodi and Wauters, 1981).

Crossreactions have been noted between *Klebsiella* K-antigens and *E. coli* K-antigens (Kauffmann, 1949) because of (in some cases at least) the horizontal transfer of the genomic region responsible for capsule synthesis (see the section Properties Relevant to Pathogenicity for Humans in this Chapter).

MOLECULAR SEROTYPING In an effort to replace classical K-serotyping, restriction of the amplified capsular antigen gene cluster was recently developed (Brisse et al., 2004a). The method enables to determine the capsular antigen without using antiserum. PCR amplification of the *cps* genomic region is followed by restriction with enzyme *HincII* and agarose gel electrophoresis, generating C-patterns. The C-patterns

obtained for strains of any K-serotype were different from those of all other K-serotypes, with only one exception (K22 and K37). More than 100 C-patterns were distinguished; in general, strains of the same K-type but belonging to distinct *Klebsiella* species showed distinct C-patterns. Only 4.5% of the strains were non-typable owing to PCR amplification failure. Non-capsulated strains were amenable to molecular K-serotyping (Brisse et al., 2004a).

PHAGE TYPING Bacteriophages have been isolated that depolymerize capsular material (Ørskov, 1984a). Different phage typing systems have been proposed (Slopek et al., 1967b; Slopek, 1978; Rennie et al., 1978; Gaston et al., 1987). These systems could type 70–96% of *Klebsiella* isolates. Reproducibility was often good when replicate testing was done immediately, and poor when replicate testing was done after a few weeks (Gaston et al., 1987). Phage typing has been compared to K-typing and re-evaluated recently (Sechter et al., 2000). The discriminatory power of phage typing was comparable to that of K-typing, but phage types were found to be less stable and reproducible. Phage typing is not used frequently; the last *Klebsiella* outbreak investigation making use of this approach was published in 1996 (French et al., 1996).

BACTERIOCIN TYPING Bacteriocins are the most abundant and diverse of the microbial defense systems (Riley and Wertz, 2002). Bacteriocins of *Klebsiella* were first characterized in detail by Hamon and Péron (1963). Bacteriocins of *Klebsiella* have been called “pneumocins” (Hamon and Péron, 1963), “klebocins” (Buffenmeyer et al., 1976; Walia et al., 1988), “klebecins” (Edmonston and Cooke, 1979a) or simply “bacteriocins of *Klebsiella*” (Hall, 1971). Bacterial isolates can be typed either by the sensitivity to bacteriocins produced by a set of strains (bacteriocinotyping) or by the pattern of growth inhibitor exerted by their bacteriocins on a set of indicator strains (bacteriocinogenotyping). About 34–51% of isolates produce bacteriocins either spontaneously or after induction by mitomycin (Hamon and Péron, 1963; Bauernfeind et al., 1981). Different bacteriocin typing systems were proposed that could type 59–97% of isolates (Slopek and Maresz-Babczyszyn, 1967a; Buffenmeyer et al., 1976; Edmonston and Cooke, 1979a; Israil, 1980b; Bauernfeind et al., 1981). Reproducibility of these systems can be poor. Reproducibility can be improved by a careful evaluation of each technique (Bauernfeind, 1984). *Klebsiella* strains have also been typed by production of and sensitivity to colicins as determined by the use of standard colicin indicator strains and colicin producing strains (Israil,

1980a). One plasmid encoding klebicin B of *K. pneumoniae* was sequenced, and it was found that klebicin B has sequence similarity to DNase pyocins and colicins, suggesting that this klebicin is a nonspecific endonuclease (Riley et al., 2001).

MULTILOCUS ENZYME ELECTROPHORESIS Multilocus enzyme electrophoresis (MLEE) consists of monitoring the variation, among strains, of the electrophoretic migration of amino acid sequence variants of a number of enzymes involved in housekeeping functions (Selander et al., 1986). In striking contrast to the situation in *E. coli* and *Salmonella*, MLEE has almost never been used for *Klebsiella* typing and population genetics, although occurrence of variation was early demonstrated among *Klebsiella* strains (Goullet, 1980). An alternative method to index MLEE variation, which involves polyacrylamide-agarose gel electrophoresis followed by electrophoretic transfers on nitrocellulose sheets, was developed (Nouvellon et al., 1994; Combe et al., 2000). To our knowledge, the method was applied only to the investigation of one outbreak of one ESBL-producing *Klebsiella* strain (Nouvellon et al., 1994). Because of the paucity of MLEE studies of *Klebsiella* species, basic aspects of their population genetics, such as the amount of genetic diversity and the evolutionary impact of genetic recombination within species, are still ignored at the present time.

MOLECULAR TYPING METHODS Molecular typing methods aim at discriminating among strains based on the differences in their genomic DNA sequence and organization (for a recent review, see Van Belkum et al., 2001). Over the last years many molecular typing methods have been applied to investigate outbreaks due to *Klebsiella* strains and to compare strains from different time points and geographic origins. Most methods rely on DNA fragment fingerprints, which can be highly discriminatory but are generally not standardized enough to allow comparison of data from distinct studies. Sequence-based methods such as multilocus sequence typing (MLST; Maiden et al., 1998), which have the advantage of standardization and portability, are only beginning to be applied to *Klebsiella*. Six genes (*tonB*, *ureD*, *tyrB*, *aroA*, *gapA* and *rpoB*) that could be included in an MLST typing scheme and have been sequenced in a number of *K. pneumoniae* strains, are available in GenBank (Z. Y. Shi, unpublished observation). A full MLST scheme based on genes *aroA*, *gapA*, *infB*, *mdh*, *pgi*, *phoE*, *rpoB* and *tonB* was just developed (S. Brisse, unpublished), and data are available on the public MLST Web site of Mark Achtman's group at (<http://web.mpiib-berlin.mpg.de/mlst/>).

PLASMID PROFILING. Plasmid DNA profiles and plasmid DNA restriction profiles have been seldom used in epidemiological investigations (Walia et al., 1988; Marranzano et al., 1996). Compared to other methods, however, plasmid profiling is particularly useful to track the spread of plasmids encoding antimicrobial resistance genes among strains and species, as opposed to strain epidemics (Bingen et al., 1993).

RANDOM PCR METHODS. Methods based on the PCR amplification of uncharacterized DNA fragments, such as random amplified polymorphic DNA (RAPD), repeat-based PCR (rep-PCR) or enterobacterial repetitive intergenic consensus sequence PCR (ERIC-PCR), present the advantage of being applicable without prior knowledge of the genome sequence and with few technical tuning steps. These methods can, therefore, be very helpful for rapid local investigations of the sources and routes of clonal spread. Applications to *Klebsiella* epidemiology have been published (Wong et al., 1994; Eisen et al., 1995; Gori et al., 1996; Lhopital et al., 1997; Shannon et al., 1998; Ben-Hamouda et al., 2003). Efforts to standardize RAPD have been made (Vogel et al., 1999). However, these methods generally suffer from poor reproducibility, especially when interlaboratory comparisons are concerned (Van Belkum et al., 2001). Multiple-primer RAPD has proved very useful as a screening method to identify divergent lineages within *K. pneumoniae* and *K. oxytoca* (Brisse and Verhoef, 2001).

PULSE-FIELD GEL ELECTROPHORESIS. Pulse-field gel electrophoresis (PFGE), or DNA macrorestriction fragment analysis, is probably the most widely used DNA fingerprinting method in bacterial typing, and this holds true for *Klebsiella* (Poh et al., 1993; Arlet et al., 1994; Gouby et al., 1994; Gori et al., 1996; Monnet et al., 1997; Toldos et al., 1997; Yuan et al., 1998; Chang et al., 2000; Nadjar et al., 2000; Sechi et al., 2001; Cheng et al., 2002; Hansen et al., 2002; Lebessi et al., 2002). It consists of cutting the genome with a restriction enzyme, followed by separation of the large fragments on an agarose gel by alternately applying two electric fields that are differently orientated. The restriction enzymes *Hae*III, *Xba*I and *Spe*I have been used in *Klebsiella*, mostly with the purpose of investigating whether clinical isolates recovered during outbreaks of ESBL-producing *klebsiellae* belonged to a single clone (see above references). PFGE data have been compared to O:K serotyping data and shown to be more discriminatory (Hansen et al., 2002). These authors remind us that serotyping cannot be replaced by PFGE, though, given the low standardization and inter-laboratory reproducibility of this latter method.

RIBOTYPING. Ribotyping, or ribosomal ribonucleic acid (rRNA) gene restriction patterns (Grimont and Grimont, 1986; Stull et al., 1988; Bingen et al., 1994; Brisse, 2003), has been used extensively to type *Klebsiella* isolates (Bingen et al., 1993; Maslow et al., 1993; Thompson et al., 1993; Arlet et al., 1994; Lhopital et al., 1997; Sader et al., 1998; Brisse et al., 2000; Sechi et al., 2001; Cheng et al., 2002; Fung et al., 2002; Yu et al., 2002). It shows excellent discriminatory power in *Klebsiella* owing to the presence of several ribosomal RNA operons in the genome. The availability of the automated method making use of the riboprinter instrument (DuPont-Qualicon, Wilmington, DE) has rendered ribotyping extremely easy to perform and, above all, makes it one of the few standardized typing methods. Indeed, ribotyping data are highly reproducible from riboprinter to riboprinter and easily portable among laboratories (Brisse et al., 2002; Brisse, 2003). Enzyme *Eco*RI is most generally used for typing purposes. One particularly useful application of ribotyping is the identification of *Klebsiella* species and phylogenetic groups (Brisse and Verhoef, 2001).

AFLP. Often taken as an abbreviation for Amplification of Fragment Length Polymorphisms, but not initially named with this in mind, AFLP was first developed as a genetic tool for plant breeders (Vos et al., 1995) and is patented by the Dutch company KeyGene N.V. (Wageningen, The Netherlands). It is based on the selective PCR amplification of restriction fragments from a total digest of genomic DNA. Its technical details and applications to microbial typing were reviewed by Savelkoul et al. (1999). Advantages of AFLP include very high discriminatory power, high reproducibility, flexibility in the sequence coverage of the genome, and the almost exclusive possibility to reamplify and sequence AFLP fragments of interest, thus facilitating the detection of DNA sequences associated with particular phenotypic traits (Van Belkum, 2003). AFLP recently has been evaluated and validated for the delineation of sets of strains implicated in clonal spread during *Klebsiella* hospital outbreaks and for the identification of *Klebsiella* species and phylogenetic groups (Jonas et al., 2004). A variation of the protocol that permits separation of AFLP fragments on agarose gels, rather than polyacrylamide gels as performed in the original method, has been developed for *Klebsiella* (Van der Zee et al., 2003).

OTHER TYPING METHODS Typing methods based on mass spectrometry are being increasingly evaluated for microbial identification, typing and proteomics (Shah et al., 2002). Only one application to *Klebsiella* was published (Jackson et al.,

1997). These methods, in particular matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry (MS), can be extremely cheap and quick compared to molecular typing methods and present the possibility to identify protein components associated with phenotypic aspects of the bacteria. However, interpretation of the fingerprints for typing purposes may remain a problem, as they may not be independent of the culture media used.

Klebsiella Components Used as Biological Models

NITROGEN FIXATION AND INTERACTION WITH PLANTS Associative nitrogen fixation is carried out by bacteria living on the roots of nonleguminous plants. *Klebsiella pneumoniae*, *K. oxytoca* or *K. planticola* are capable of fixing nitrogen and are classified as associative nitrogen fixers, or diazotrophs (Mahl et al., 1965; Ladha et al., 1983). Endophytic *K. pneumoniae* strains found within maize are diazotrophic (Palus et al., 1996), and one studied strain was able to produce dinitrogenase reductase protein within roots, as long as a carbon source was added to the maize seedlings (Chelius and Triplett, 2000). These endophytic strains belong to *K. pneumoniae* phylogenetic group KpIII (Brisse and Verhoef, 2001) as shown by Dong et al. (2003).

Nitrogen fixation is catalyzed by the enzyme nitrogenase in the absence of combined nitrogen and under anaerobic conditions (Postgate, 1982; Schmitz et al., 2002). Nitrogen fixation is catalyzed by the enzyme complex nitrogenase and requires high amounts of energy in the form of two ATP molecules for each electron transferred to the catalytic site (Schmitz et al., 2002). In the facultative anaerobe *K. pneumoniae*, nitrogen fixation occurs only in anaerobic or microaerobic conditions. Low O₂ concentrations enhance nitrogenase synthesis; higher O₂ concentrations inhibit synthesis and irreversibly inactivate the enzyme complex (Hill et al., 1984). Molybdenum is required for the activity of nitrogenase (Shah and Brill, 1977; Shah et al., 1984), and it is found in this enzyme as part of low-molecular-weight cofactors (Johnson, 1980). Two different molybdenum-containing cofactors have been described: iron-molybdenum cofactor (FeMo-co) contained in component I (Shah and Brill, 1977), and molybdenum cofactor (Mo-co; Johnson, 1980). FeMo-co can activate in vitro nitrogenase from certain *nif* mutants (Roberts et al., 1978) and is believed to be an active site of nitrogen reduction (Shah et al., 1978). Nitrogenase is composed of two different proteins—nitrogenase component I and nitrogenase component II. The two subunits of component I are coded by the genes *nifK* and *nifD*, which share

an operon with the component II gene (*nifH*). There are at least 17 contiguous nitrogen fixation (*nif*) genes clustered on the chromosome and organized into eight operons, whose products are likely to be required for the synthesis and assembly of an active nitrogen-fixing system (Roberts and Brill, 1981; Beynon et al., 1983; Ausebel, 1984). These genes include *nifHDK* (nitrogenase structural components); *nifF* and *nifJ* (electron transport components); *nifQ*, *nifB*, *nifE*, *nifN* and *nifV* (FeMo-co biosynthetic components); *nifA* and *nifL* (positive and negative regulatory elements); *nifM* (Fe protein maturation component); and *nifY*, *nifX*, *nifU* and *nifS* (functions not known).

The genetic control of nitrogen fixation is complex (Roberts and Brill, 1981; Gussin et al., 1986) and has been reviewed recently (Schmitz et al., 2002). The products of the *nifLA* operon regulate the transcription of the other operons. NifA is a transcriptional regulator that acts by promoting the formation of transcriptionally-productive open complexes between σ -54 and the polymerase holoenzyme (Morett and Buck, 1989; Hoover et al., 1990). NifL modulates the activity of NifA by direct protein-protein interaction in response to the presence of combined nitrogen and molecular oxygen (Henderson et al., 1989; Govantes et al., 1998). The primary oxygen sensor appears to be the global regulator Fnr (fumarate nitrate reduction regulator), which transduces the signal to NifL (Grabbe et al., 2001). The nitrogen signal is mediated via the GlnK protein, which relieves NifL inhibition under nitrogen-limiting conditions (He et al., 1998; Jack et al., 1999). *Klebsiella pneumoniae* apparently senses external nitrogen limitation as a drop in the internal glutamine pool (Schmitz, 2000).

UREASE Urease from *K. pneumoniae* plays an important role in nitrogen metabolism and is intensely studied as a model to understand urease catalytic activity. This nickel-containing enzyme hydrolyzes urea to ammonia and carbon dioxide. Its regulation has been characterized (Friedrich and Magasanik, 1977; Magasanik, 1982), and the three-subunit enzyme shown to contain four nickel ions per native molecule (Todd and Hausinger, 1987). Urease was localized to the cytoplasmic portion of the cell (Mulrooney et al., 1989). The crystal structure of *K. pneumoniae* urease has been the first to be determined, and revealed a unique dinuclear active site with the metal ions bridged by a carbamylated lysine residue (Jabri et al., 1995; Pearson et al., 1997). Proper assembly of this metallocenter is a key step for maturation of urease and, in *K. pneumoniae*, involves the products of the *ureD*, *ureE*, *ureF* and *ureG* accessory genes located

adjacent to the structural genes (*ureA*, *ureB* and *ureC*; Soriano and Hausinger, 1999).

SECRETION Pullulanase (pullulan 6-glucanohydrolase), an extracellular starch-debranching enzyme produced by some strains of *K. pneumoniae*, hydrolyzes the (1-6)- α -glucosidic linkages in pullulan and starch to form maltotriose (Wöhner and Wöhner, 1978). Pullulanase has been intensely analyzed as a model protein substrate for the general secretory pathway of Gram-negative bacteria (Pugsley et al., 1997). Pullulanase is first exported to the cell surface where it accumulates until it is released into the growth medium. Production is induced by the substrate of the enzyme (pullulan), or a product of the enzyme (maltose or maltodextrin) but is repressed in the presence of glucose. The structural gene for pullulanase was studied by Michaelis et al. (1985). The nucleotide sequence of the pullulanase gene, required for pullulanase secretion, was determined by Katsuragi et al. (1987) for *pulA* and by Pugsley and Reyss (1990) for *pulL*, *pulM*, *pulN* and *pulO*. Another starch utilization pathway was discovered more recently in *K. oxytoca* (Fiedler et al., 1996). It involves the extracellular conversion of starch to cyclodextrins, uptake of these, and intracellular linearization by a cyclodextrinase.

PECTIN DEGRADATION *Klebsiella oxytoca* isolates (previously, indole-positive *K. pneumoniae*), without known phytopathogenic relationship to plants, are able to digest the kind of calcium-stabilized polygalacturonate gels used in studies of soft rot *Erwinia* species (Von Riesen, 1976). These bacteria showed detectable, albeit generally weak, ability to digest polygalacturonic (pectic) acid (Starr et al., 1977). Analyses of the pectolytic enzyme contents of the cells and culture supernatants of *K. oxytoca* revealed that readily detectable quantities of cell-bound polygalacturonic acid *trans*-eliminase and hydrolytic polygalacturonase were found but not excreted rapidly and massively into the growth medium, unlike soft-rot *Erwinia* species. The *pehX* gene, encoding the enzyme polygalacturonase that cleaves a polygalacturonic chain of demethoxylated pectin, was cloned (Kovtunovych et al., 2000) and used as a basis for a *K. oxytoca*-specific PCR assay (Kovtunovych et al., 2003).

HISTIDINE DECARBOXYLASE Inducible histidine decarboxylase (HDC) from *K. planticola* is responsible for histamine formation from histidine in food products, which can result in a syndrome called "histamine fish poisoning" (Guirard and Snell, 1987). HDC requires pyridoxal 5'-phosphate as a coenzyme and decarboxylates

only L-histidine among the amino acids derived from protein (Guirard and Snell, 1987). The genes encoding pyridoxal phosphate-dependent histidine decarboxylases from *K. planticola* and *E. aerogenes* have been cloned (Kamath et al., 1991). Although histamine fish poisoning was previously attributed to *K. pneumoniae* and *K. oxytoca*, Kanki et al. showed that this conclusion was due to misidentification of *K. planticola* and *K. ornithinolytica* (Kanki et al., 2002).

Klebsiella and Biotechnology

BIOCONVERSIONS *Klebsiella pneumoniae* has the ability to grow fermentatively on glycerol without an exogenous hydrogen acceptor (Lin, 1976). This is achieved by the cooperation of two pathways specified by the *dha* regulon (Lin, 1976). In the oxidative pathway, glycerol is dehydrogenated by the nicotinamide adenine dinucleotide (NAD⁺)-linked glycerol dehydrogenase to dihydroxyacetone, which is then phosphorylated by the dihydroxyacetone kinase to dihydroxyacetone phosphate. In the reductive pathway, glycerol dehydratase produces 3-hydroxypropionaldehyde, which is converted to 1,3-propanediol (lost to the growth medium) by a NADH-linked oxidoreductase (Lin, 1976). In the presence of semicarbazide and with adjusted aerobic and substrate conditions, 3-hydroxypropionaldehyde can be accumulated from glycerol by *K. pneumoniae* (Slininger and Bothast, 1985). This bioconversion is interesting since the chemical oxidation of 3-hydroxypropionaldehyde leads to acrylic acid, an industrially important polymerizable monomer currently derived from petroleum (Slininger and Bothast, 1985).

Production of 1,3-propanediol by *Klebsiella* (Homann et al., 1990) has attracted renewed interest because of the industrial need to find precursor monomers for the synthesis of a new polyester used in carpets and textiles, polytrimethylene terephthalate (Huang et al., 2002). 1,3-Propanediol is the characteristic fermentation product of glycerol and is formed together with acetic acid in a ratio of 2 to 1. *Klebsiella pneumoniae* can shift from acetic acid to 2,3-butanediol formation under conditions of decreased pH (Biebl et al., 1998). However, the cost of glycerol being elevated, cost-effective production of 1,3-propanediol can only be achieved if a cheaper substrate, such as glucose, is used. Efforts are being made to combine the pathway of glucose to glycerol with that from glycerol to 1,3-propanediol, either by combining microorganisms in simultaneous or two-step cultures or by creating recombinant microorganisms with both pathways (Biebl et al., 1999; Huang et al., 2002).

The production of 2,3-butanediol from lignocellulosic wastes is an alternative approach in the

conversion of biomass substrates to liquid fuels and chemical feedstocks (Johansen et al., 1975; Magee and Kosaric, 1987). To be economically attractive, the efficient utilization of all the available substrates in the cellulose and hemicellulose component of the biomass must be achieved (Yu and Saddler, 1983). Hemicellulose makes up 30–40% of agricultural residues. *Klebsiella pneumoniae* or *K. oxytoca* have been shown to utilize all of the major sugars (hexoses, pentoses, and certain disaccharides) and uronic acids derived from the hydrolysates of hemicellulosic and cellulosic materials (Yu and Saddler, 1983). When *K. oxytoca* (referred to as *K. pneumoniae*) was grown under finite air conditions in the presence of acetic acid, 50 g of D-glucose and D-xylose per liter could be converted to 25 and 27 g of butanediol per liter, respectively (Yu and Saddler, 1983). A maximum of 84.2 g of butanediol per liter was obtained with an initial glucose concentration of 262.6 g per liter (Qureshi and Cheryan, 1989). By a sequential coculture approach involving a cellulolytic and xylanolytic fungus, *Trichoderma harzianum* and *K. oxytoca* (referred to as *K. pneumoniae*), cellulose and hemicellulose substrates (or steam-exploded wood) were converted to 2,3-butanediol (Yu et al., 1985). Alternatively, *K. planticola* can produce large amounts of ethanol instead of butanediol after genetic recombination involving a multicopy plasmid carrying the pyruvate decarboxylase gene from *Zymomonas mobilis* (Tolan and Finn, 1987). The production of butanediol and ethanol is seen as a way to utilize pyruvate that avoids the production of acidic end products. Production of butanediol is enhanced in the presence of acetate, when oxygen is limited and the pH lowered. The pathway that utilizes two moles of pyruvate to produce one mole of butanediol involves three enzymes: α -acetolactate synthetase, α -acetolactate decarboxylase, and acetoin reductase (Magee and Kosaric, 1987). The genes encoding these enzymes are organized in an operon (*budABC*) and have been cloned and sequenced in *K. terrigena* (Blomqvist et al., 1993) and *K. pneumoniae* (Wardwell et al., 2001). A *Clostridium acetobutylicum* strain, into which the acetoin reductase gene from *K. pneumoniae* was transferred, produced butanediol only if acetoin was added to the culture medium (Wardwell et al., 2001). The *budABC* operon is under the control of BudR, a transcriptional regulator belonging to the LysR family, which was cloned and sequenced in *K. terrigena* (Mayer et al., 1995). The gene *budR* is separated from the *budABC* operon by a 106-bp intergenic region and is inversely oriented. BudR activity is induced by acetate and repressed by the global regulator Fnr (fumarate nitrate reduction regulator; Mayer et al., 1995).

The crystal structure of *K. pneumoniae* acetolactase synthase was determined (Pang et al., 2004).

BIOREMEDIATION Many environmental *Klebsiella* strains have been found with various metabolic properties that are interesting for bioremediation. Two early examples include herbicide and pesticide degradation. First, a soil isolate identified as *K. pneumoniae* subsp. *ozaenae* (but possibly rather a *K. pneumoniae* subsp. *pneumoniae* with low metabolic activity), which was found to convert 0.05% bromoxynil (3, 5-dibromo-4-hydrobenzotrile), a widely used herbicide, to 3, 5-dibromo-4-hydrobenzoic acid, and utilize the liberated ammonia as sole nitrogen source (McBride et al., 1986). This transformation is due to a plasmid-encoded nitrilase highly specific for bromoxynil (Stalker et al., 1987). A gene, designated “*bxn*,” encoding the bromoxynil-specific nitrilase, was cloned (Stalker et al., 1987). Second, *K. pneumoniae* was found to be able to reduce the organophosphorus pesticide fensulfothion to fensulfothion sulfide and 4-methylsulfinylphenol to 4-methylthiophenol, under oxygen limitation (Mac Rae and Cameron, 1985). More recently, *Klebsiella* strains were isolated with potential for bioremediation of phenol (Heesche-Wagner et al., 1999), endosulfan (Kwon et al., 2002), mercury (Essa et al., 2002), nitroglycerin (Marshall and White, 2001), cadmium (Sharma et al., 2000), aliphatic and aromatic nitriles (Nawaz et al., 1992), and acrylonitrile (Nawaz et al., 1991).

The Genus *Enterobacter*

FRANCINE GRIMONT AND PATRICK A.D. GRIMONT

Introduction

The genus *Enterobacter* was first proposed by Hormaeche and Edwards (1960a). However, the history of some species now placed in the genus *Enterobacter* can be traced, albeit with some confusion, to the end of the 19th century. “*Bacillus lactis aerogenes*” was isolated by Escherich (1885) from milk and renamed “*Bacillus aerogenes*” by Kruse (1896) and “*Aerobacter aerogenes*” by Beijerinck (1900). Until 1955, differentiation of this organism from Friedländer’s bacillus (now called *Klebsiella pneumoniae*) was not clear, and most authors considered “*B. lactis aerogenes*” or “*Aerobacter aerogenes*” to be either nonmotile or to contain both motile and nonmotile strains (Grimbert and Legros, 1900; Edwards and Fife, 1955). This led Edwards and Fife (1955) to state that “*A. aerogenes*” strains were in fact *Klebsiella* strains.

“*Bacterium cloacae*” was described by Jordan (1890) and transferred to a new genus “*Cloaca*” as “*Cloaca cloacae*” by Castellani and Chalmers (1920). In the first edition of *Bergey’s Manual* (Bergey et al., 1923), this species was transferred to the genus “*Aerobacter*” as “*A. cloacae*.” Since “*Aerobacter aerogenes*” was at that time indistinguishable from *Klebsiella pneumoniae*, Edwards and Fife (1955) proposed that the species “*A. aerogenes*” not be used, although disappearance of the type species (“*A. aerogenes*”) implied disappearance of the genus (“*Aerobacter*”). Because of this, two solutions were suggested for “*A. cloacae*”: 1) the reintroduction of the genus “*Cloaca*” with the species “*Cloaca cloacae*” (reference is not an exact match Kauffman, 1954); and 2) the redefinition of the genus “*Aerobacter*” with “*A. cloacae*” as type species (Edwards and Fife, 1955). However, this latter proposal did not conform to the rules of nomenclature.

A significant step forward occurred when Møller (1955) devised some simple methods for testing amino acid decarboxylases. Since the “*Cloaca*” group was arginine-positive it could

now easily be distinguished from the *Klebsiella* group, which was arginine-negative. This led to the finding of motile strains of the “*Cloaca*” group, which were arginine-negative and produced gas from inositol and glycerol (Hormaeche and Munilla, 1957). These strains were called “*Cloaca B*” (arginine-positive strains forming the “*Cloaca A* group”). Then, after reexamination of many cultures using the decarboxylase test, Hormaeche and Edwards (1958) redefined the genus “*Aerobacter*” to include two species, “*A. aerogenes*” (“*Cloaca B*”) and “*A. cloacae*” (“*Cloaca A*”), with the type species reaffirmed as “*A. aerogenes*.”

Grimes and Hennerty (1931) described a group of strongly proteolytic strains they named “*Aerobacter liquefaciens*.” However, this name was illegitimate since the same name had been used by Beijerinck (1900) for bacteria which could have been aeromonads, so that Grimes (1961) renamed his group as “*Aerobacter lipolyticus*.” Eventually, however, Beijerinck’s “*A. liquefaciens*” was placed on the list of rejected names (Judicial Commission, 1973), and “*A. liquefaciens*” Grimes and Hennerty became accepted.

In an attempt to avoid confusion resulting from the reclassification in the genus *Klebsiella* of many nonmotile strains previously labeled “*A. aerogenes*,” Hormaeche and Edwards (1960a 1960b) proposed a new genus *Enterobacter* as a substitute for “*Aerobacter*.” This genus was then composed of *E. cloacae* (the type species) and *E. aerogenes*. In 1963, the Judicial Commission of the International Committee on Nomenclature of Bacteria placed the name *Enterobacter* on the list of conserved names (Judicial Commission, 1963).

“*Aerobacter liquefaciens*,” included in the genus *Enterobacter* as *E. liquefaciens* (reference is not an exact match Edwards and Ewing, 1972), was then transferred to the genus *Serratia* as *S. liquefaciens* (Bascomb et al., 1971). DNA-relatedness studies have clearly demonstrated it to be a member of the genus *Serratia* (Steigerwalt et al., 1976).

A group of strains named *Hafnia* by Møller (1954) was included in the genus *Enterobacter* *E. hafniae* (Ewing and Fife, 1969) although it was

given in the 8th edition of *Bergey's Manual* (Buchanan and Gibbons, 1974) as *Hafnia alvei*. DNA-relatedness studies (Steigerwalt et al., 1976) clearly required the separation of *Hafnia alvei* from the genus *Enterobacter*.

The genus *Erwinia* has long been a depository for plant-associated members of the Enterobacteriaceae (see Chapter 154). Several species of this genus were found to be phenotypically similar to *Enterobacter* species (*Erwinia herbicola*, *E. ananas*, *E. uredovora*, *E. milletiae*, *E. dissolvens*, *E. nimipressuralis*) (reference is not an exact match Lelliott, 1974; reference is not an exact match Lelliott and Dickey, 1984) or highly related to *Enterobacter* species by DNA hybridization (*Erwinia dissolvens*, *E. nimipressuralis*) (Steigerwalt et al., 1976).

The other species now classified in the genus *Enterobacter* have been described after delineation by DNA-DNA hybridization. The species (and their synonyms) presently composing the genus *Enterobacter* are:

1. *Enterobacter cloacae* (Jordan) Hormaeche and Edwards 1960a; "*Bacillus cloacae*" Jordan 1890; "*Aerobacter cloacae*" (Jordan) Hormaeche and Edwards 1958. The type strain is strain ATCC 13047 (= CDC 279-56, NCTC 442.68, CIP 60.85). This strain is very close by DNA hybridization to the type strain of *E. dissolvens*.

2. *Enterobacter aerogenes* (Kruse) Hormaeche and Edwards 1960a; "*Bacillus aerogenes*" Kruse 1896; "*Aerobacter aerogenes*" (Kruse) Hormaeche and Edwards 1958; *Enterobacter aerogenes* (Hormaeche and Edwards 1960a 1960b); *Klebsiella mobilis* Bascomb et al. 1971. The type strain is strain ATCC 13048 (= CDC 819-56, NCTC 10006, CIP 60.86).

3. *Enterobacter gergoviae* Brenner et al. 1980; *Enterobacter* sp. urease positive (Richard et al., 1976). The type strain is strain ATCC 33028 (= CDC 604-77, CIP 76.01).

4. *Enterobacter sakazakii* Farmer et al. 1980; yellow-pigmented *Enterobacter cloacae* (Steigerwalt et al., 1976). The type strain is strain ATCC 29544 (= CDC 4562-70).

5. *Enterobacter intermedium* Izard, Gavini, and Leclerc 1980; *Enterobacter* group H₁ (Gavini et al., 1976; Izard et al., 1979). The type strain is strain ATCC 33110 (= CUETM 77-130, CIP 79.27).

6. *Enterobacter amnigenus* Izard et al. 1981; *Enterobacter* group H₃ (Gavini et al., 1976). The type strain is strain ATCC 33072 (= CUETM 77-118).

7. *Enterobacter cancerogenus* (Urosevic) Dickey and Zumoff 1988; *Erwinia cancerogena* Urosevic, 1966. The type strain is ATCC 33241 (= NCPPB 2176). *Enterobacter taylorae* Farmer et al. 1985 (type strain, ATCC 35317 = CDC

2126-81) was found to be a junior synonym of *E. cancerogenus* (Grimont and Ageron, 1989).

8. *Enterobacter asburiae* Brenner et al. 1986; enteric group 17 (Farmer et al., 1985a). The type strain is ATCC 35953 (= CDC 1497-78).

9. *Enterobacter nimipressuralis* (Carter) Brenner et al. 1986; *Erwinia nimipressuralis* Carter 1945. The type strain is strain ATCC 9912.

10. *Enterobacter dissolvens* (Rosen) Brenner et al. 1986; "*Pseudomonas dissolvens*" Rosen 1922; "*Aerobacter dissolvens*" (Rosen) Waldee 1945; *Erwinia dissolvens* (Rosen) Burkholder 1948. The type strain is ATCC 23373. The type strain belongs in the *Enterobacter cloacae* complex.

11. *Enterobacter agglomerans* (Beyerinck 1888) Ewing and Fife 1972; "*Bacillus agglomerans*" Beijerinck 1888; *Erwinia lathyri* (Manns and Taubenhaus) Magrou 1937; *Erwinia herbicola* (Löhnis) Dye 1964; *Erwinia milletiae* (Kawakami and Yoshida) Magrou 1937; *Pantoea agglomerans* (Beijerinck) Gavini et al. 1989. The type strain is ATCC 27155 (= CDC 1461-67, CIP 57.51).

12. *Enterobacter hormaechei* O'Hara et al. 1989; Enteric group 75 (O'Hara et al., 1989). The type strain is ATCC 49162.

Remaining Taxonomic Problems in the Genus *Enterobacter*

DNA-relatedness studies of some early described species in the genus *Enterobacter* (*E. aerogenes*, *E. agglomerans*, and *E. cloacae*) unveiled some previously unsuspected problems in the placement of these species.

PRECISE POSITION OF *E. AEROGENES* WITH RESPECT TO THE GENUS *KLEBSIELLA* By DNA hybridization, *E. aerogenes* is closer to *Klebsiella pneumoniae* (about 55% relatedness) than to *E. cloacae* (about 45% relatedness) (Brenner et al., 1972; Steigerwalt et al., 1976). In a numerical taxonomy study (Bascomb et al., 1971), *E. aerogenes* was so close to the genus *Klebsiella* that transfer of this species to the genus *Klebsiella* was proposed. Since the name "*K. aerogenes*" had been used for bacteria which are undistinguishable from *K. pneumoniae* by DNA hybridization, the name *K. mobilis* was proposed for *E. aerogenes* (Bascomb et al., 1971). Carbon source utilization patterns of *E. aerogenes* are also closer to those of *Klebsiella* species than to those of *Enterobacter* species (P.A.D. Grimont, unpublished observations). In the authors' opinion, *E. aerogenes* can reasonably be placed in the genus *Klebsiella*. The problem is only a nomenclatural one.

HETEROGENEITY OF *ENTEROBACTER AGGLOMERANS* *E. agglomerans* comprises a very complex group of environmental bacteria which may cause opportunistic infections. The name covers many

(20 to 40 or more) genomic groups (Brenner et al., 1984) or phenons (Gavini et al., 1983; Verdonck et al., 1987). In addition to this diversity, strains of the *E. agglomerans* complex are not closely related to *E. cloacae* (the type species of the genus *Enterobacter*) by DNA hybridization. Some groups in this complex have been individualized as new genera (*Rahnella aquatilis*, *Ewingella americana*, *Leclercia adecarboxylata*). There apparently is confusion in the literature, and a close examination of published papers for the presence of commonly studied strains is needed to extract convergent pieces of information.

Table 1 lists the phenons and DNA groups that have been proposed. The numerical study of Gavini et al. (1983), based on 169 strains, yielded five phenons (A to E). Phenon A corresponded to *Erwinia carotovora*. Phenon B, which included strains of the *Enterobacter agglomerans* complex, was split into nine smaller phenons (B1 to B9). Phenon B4 contained the type strains of *Erwinia herbicola* and *Erwinia milletiae*. Phenon B8 contained the type strain of *Erwinia ananas* and a reference strain of *Erwinia uredovora*. Phenon C corresponded to *Rahnella aquatilis*. Phenon D was split into three smaller phenons (D1 to D3), phenon D2 corresponding to *Enterobacter sakazakii*. Phenon E was split into five smaller phenons (E1 to E5), phenon E5 containing strains previously identified as *Escherichia adecarboxylata*. A larger numerical study (Verdonck et al., 1987), based on 529 strains including many type and reference strains, led to the distribution of 66 strains of the *Enterobacter agglomerans* complex into 21 phenons. The correspondence between phenons from both studies (Gavini et al., 1983 and Verdonck et al.,

1987) is given in Table 1. The DNA-relatedness work of Brenner et al. (1984) showed the extreme genomic diversity of the *Enterobacter agglomerans* complex since, of 124 strains studied, 90 fell into 13 DNA groups (I to XIII), and 34 strains did not fit into any group. Furthermore, four groups (V, XI, XII, and XIII) were heterogeneous with respect to the thermal stability of heteroduplexes (ΔT_m values). An interesting finding was that aerogenic (gas-producing) strains and anaerogenic strains were not found in the same hybridization group.

By DNA hybridization, Lind and Ursing (1986) identified 52 of 86 clinical isolates with *Enterobacter agglomerans* sensu stricto. In the same study, they demonstrated the synonymy of *Enterobacter agglomerans*, *Erwinia herbicola*, and *Erwinia milletiae*. This synonymy was confirmed by Beji et al. (1988) who, in addition, identified DNA group XIII (Brenner et al., 1984) with *Enterobacter agglomerans* sensu stricto.

To separate *Enterobacter agglomerans*/*Erwinia herbicola* from the genera *Enterobacter* and *Erwinia*, the new genus *Pantoea* has been proposed, with *P. agglomerans* as type species (Gavini et al., 1989). Strains of DNA group III (Brenner et al., 1984) or phenon 8 (Verdonck et al., 1987) were proposed as the new species *Pantoea dispersa* (Gavini et al., 1989). The DNA groups closest to *Enterobacter agglomerans* (*Pantoea agglomerans*) are DNA groups II, III, IV, V, and VI (Lind and Ursing, 1986). It is interesting that strains of group II to VI and XIII are characterized by the presence of a glucose oxidation pathway producing 2-ketogluconate from glucose (Bouvet et al., 1989). This finding has been extended to DNA group I (P.A.D. Grimont,

unpublished observations). Thus, the genus *Pantoea* can be envisioned to include DNA groups I, II, IV, V, and VI ("*Pantoea ananas*"), in addition to groups XIII (*P. agglomerans*) and III (*P. dispersa*).

DNA group XI (Brenner et al., 1984) was identified with *Escherichia adecarboxylata* by DNA hybridization (Izard et al., 1985). *Escherichia adecarboxylata* was recently transferred to a new genus *Leclercia* as *L. adecarboxylata* (Tamura et al., 1986). DNA group VII (Brenner et al., 1984) was found close to (but distinct from) *Escherichia (Leclercia) adecarboxylata* (Izard et al., 1985). In our laboratory, strains of DNA group VII were found indistinguishable from strains of phenon E4 (Gavini et al., 1983) by carbon source utilization tests (P.A.D. Grimont, unpublished observations). Thus, DNA group VII is a good candidate as a new species of *Leclercia*.

DNA group VIII (Brenner et al., 1984) was found to be 64% related to *Erwinia persicinus* (a close relative of *Erwinia rhapontici*), and in a numerical taxonomy study, DNA group IX (Brenner et al., 1984) was close to *Rahnella aquatilis* (Verdonck et al., 1987).

More work is needed to characterize all the species in the *E. agglomerans* complex and to assign them to *Pantoea*, *Leclercia*, and related genera.

HETEROGENEITY OF *ENTEROBACTER CLOACAE*

Early DNA-relatedness studies on *E. cloacae* (Steigerwalt et al., 1976) showed the genomic heterogeneity of this nomen-species. In work done in our laboratory (P.A.D. Grimont, unpublished observations) on 49 strains previously identified as *E. cloacae*, 45 strains fell into five DNA relatedness groups (1 to 5). Group 1 contained only three strains, including the type strains of *E. cloacae* and *E. dissolvens*. Reassociated DNA from these type strains showed some divergence (ΔT_m values of 4.5°C). In spite of a search for similar strains in our large laboratory collection, no other strain of group 1 could be found. Group 2 contained seven strains, including reference strain CDC 1347-71 (Steigerwalt et al., 1976). Group 3 contained 15 strains including the type strain of *Enterobacter hormaechei*. This group was slightly heterogeneous with ΔT_m values ranging from 0.0 to 4.0°C. Group 4 contained 17 strains and could be split into three subgroups on the basis of ΔT_m values (0.0 to 2.5°C within subgroups and 4.0 to 6.5°C between subgroups). Subgroup 4a contained the type strain of *Enterobacter asburiae*. Group 5 (earlier referred to as group 6 [Bouvet et al., 1989]) contained three nitrogen-fixing strains.

The three following problems are raised by this unpublished study. The first problem deals

with *E. hormaechei*. A group of similar strains (enteric group 75), found to differ phenotypically from *E. cloacae* was shown to be genomically distinct from the type strain of *E. cloacae* and thus described as a new species, *E. hormaechei* (O'Hara et al., 1989). In our group 3, we found only one strain phenotypically similar to *E. hormaechei*. All other strains of group 3 fitted the classical definition of *E. cloacae* (Richard, 1984). Group 3 strains (including *E. hormaechei*) were found to produce an active glucose dehydrogenase, and this property differentiates group 3 from the other groups in the *E. cloacae* complex (Bouvet et al., 1989 and P.A.D. Grimont, unpublished observations). Group 3 should be named *E. hormaechei*, and the species definition should be amended.

The second problem deals with *E. asburiae*. Enteric group 17 differed from *E. cloacae* by some phenotypic features and DNA hybridization showed enteric group 17 (*E. asburiae*) to be distinct from the type strain of *E. cloacae*. Our subgroup 4a is genomically and phenotypically identical with *E. asburiae*. However, subgroups 4b and 4c are less differentiable from *E. cloacae* by phenotypic characteristics. Group 4 (including subgroups 4a, 4b, and 4c) should be called *E. asburiae* and the species definition should be amended.

The third problem is in fact the cause of the other two. The choice of the neotype strain for *E. cloacae* was unfortunate. This strain was isolated from cerebrospinal fluid, which is not the usual habitat of what is currently known as *E. cloacae*. Either the nomenclatural rules should be observed, and *E. cloacae* (our group 1) will disappear from routine clinical laboratory work (because most strains presently labeled *E. cloacae* are in fact *E. hormaechei* or *E. asburiae*), or the type strain is changed for a strain from our group 2 (which can be encountered in clinical microbiology, although less frequently than *E. hormaechei* and *E. asburiae* genomic species).

Ecology and Epidemiology

Ecological information about the *Enterobacter* species is clouded by uncertainties relative to the delineation and recognition of species within the *E. agglomerans* and *E. cloacae* complexes so that current ideas of ecology and epidemiology given below may become inaccurate when the above-mentioned complexes are resolved into many species.

Enterobacter species are found in the natural environment in habitats such as water, sewage, vegetables, and soil. Before the widespread use of antibiotics, *Enterobacter* species were rarely found as pathogens, but these organisms are now

increasingly encountered, causing nosocomial infections such as urinary tract infections and bacteremia (reference is not an exact match Eichhoff et al., 1966). In addition, they occasionally cause community-acquired infections. In 1975 in the United States, *Enterobacter* species accounted for 4.6% of all pathogens causing infections and accounted for 5.7% of all cases of primary bacteremia (Center for Disease Control, 1977). In 1984, *Enterobacter* species accounted for 5.9% of all nosocomial infections in U.S. hospitals and 6.3% of all nosocomial bacteremia (Centers for Disease Control, 1984).

Older reports on *Klebsiella-Enterobacter* infections were taxonomically imprecise. Some laboratories used one name (*Enterobacter*) for an organism isolated from urine and another name (*Klebsiella*) for the identical organism isolated from sputum. Other laboratories based the identification on the colony type: mucoid colonies were designated *Klebsiella* and nonmucoid colonies were reported as *Enterobacter* (Brenner, 1981).

E. cloacae occurs as a commensal in water, sewage, soil, meat, hospital environments, the skin, and in the intestinal tracts of humans and animals. Among 234 patients, the rate of stool carriage of *E. cloacae* on admission to the hospital was 2.6%. This rate increased to 4% after antibiotic therapy (Rose and Schreier, 1968). In a large European study, *E. cloacae* was the most prevalent Gram-negative isolate colonizing the feces of the leukemic patients (van der Waag et al., 1977). Rosenthal and Tager (1975) found isolates of *E. cloacae* in the pharynx of three of 29 normal persons.

E. cloacae infections are endemic in some hospitals. In 1966, this organism tended to colonize rather than infect hospitalized patients (Rose and Koch, 1966). At Boston City Hospital, *E. cloacae* was responsible for a variety of nosocomial and, occasionally, community-acquired infections. This species was more prevalent than *E. aerogenes* (Dans et al., 1970). In a study of infections in patients with nonlymphocytic leukemia, *E. cloacae* produced two of 87 nosocomial infections and one of 44 cases of bacteremia (Alexander, 1979). *E. cloacae* has been found in a variety of infections such as endocarditis, ventriculitis, meningitis, arthritis or osteomyelitis, urinary tract infections, and pneumonia (reviewed by John et al., 1982). *E. cloacae* bacteremia was first reported at Boston City Hospital (Maiztegui et al., 1965). Working at a large metropolitan medical center, Fuchs (1979) found isolates of *E. cloacae* in 1.8% of postoperative wound infections, in 2.9% of respiratory infections, and in 2.2% of urinary tract infections, but none among 163 blood infections. At the Manhattan Veterans Hospital in 1973–1974, of 17 bacteremic patients,

six were infected with gentamycin-resistant *E. cloacae*, and two of the six died (Richmond et al., 1975). This species has been endemic at a medical center hospital and caused 4.5% of all cases of bacteremia in 1978 (John et al., 1982). *E. cloacae* bacteremia occurs in burn units. Patients often have multiple sites (urine, wound, sputum) colonized before bacteremia develops (John et al., 1982). In a study of 41 patients burnt in military action, *Enterobacter* was the fifth most common organism colonizing or infecting burn wounds (Sidi et al., 1977). In a recent study, *E. cloacae* accounted for 29 of 58 episodes of *Enterobacter* bacteremia and 24 of 42 nosocomial *Enterobacter* bacteremia, and the most common portal of entry was the lungs (Watanakunakorn and Weber, 1989). *E. cloacae* was spread by contaminated hands of personnel and by cross-contamination of hydrotherapy water in an outbreak of infections which occurred in a burn center (Mayhall et al., 1979). Heavily colonized stools of premature infants were the source of one epidemic (Powell et al., 1980).

Contaminated medicinal agents can be sources of outbreaks. Maki and Martin (1975) showed that *E. cloacae*, *E. agglomerans*, and *Serratia marcescens* multiplied in 5% dextrose solution at 25°C better than did other members of the Enterobacteriaceae. *E. cloacae* has produced epidemics associated with contaminated benzalkonium chloride (Malizia et al., 1960), ice (Newson, 1968), platelets (Buchholz et al., 1970), pressure monitoring devices (Weinstein et al., 1976; Borobio and Perea, 1975), and hemodialysis (Buxton et al., 1978). Maki et al. (1976) reported on a nationwide epidemic in the United States caused by contaminated intravenous fluid, which caused 163 cases of *E. cloacae* bacteremia in 25 hospitals, with a mortality rate of 7.8%.

E. aerogenes occurs in water, sewage, soil, dairy products, and the feces of humans and animals. Platt et al. (1976) described the prevalence of *E. aerogenes* strains in the preputial flora of healthy stallions. Among 234 patients, the rate of stool carriage of *E. aerogenes* on admission to the hospital was 3.4%. This rate increased to 6% after antibiotic therapy (Rose and Schreier, 1968).

E. aerogenes produces infections and bacteremia in both hospitalized and nonhospitalized patients. In a neurosurgical clinic, *E. aerogenes* caused 9.8% of infections in 1972 (John et al., 1982). *E. aerogenes* bacteremia was associated with contaminated intravenous fluid in pediatric patients (Edwards et al., 1978). In an Ohio hospital, *E. aerogenes* accounted for 25 of 58 episodes of bacteremia and 17 of 42 nosocomial bacteremia (Watanakunakorn and Weber, 1989).

The *Enterobacter agglomerans* complex is ubiquitous in the environment. This species pre-

dominates on the leaf and bract of pre- and post-senescent cotton plants (DeLucca and Palmgren, 1986). The main species of Gram-negative bacteria found in cotton dusts in mills is *E. agglomerans* (Haglund et al., 1981). The following occurrences were discussed by Slade and Tiffin (1984). Strains of *Enterobacter agglomerans*/*Erwinia herbicola* are found on the aerial surfaces of plants and within healthy plant tissues and seeds. Nitrogen-fixing strains have been found in the rhizosphere of wheat and sorghum. In fact, these bacteria are typical of the innermost part of the rhizosphere of wheat (Kleeberger et al., 1983). Strains of this complex have been isolated from water, papermill-process water, soil, and decaying wood. They are frequently isolated from damaged plant tissues and lesions although they are rarely considered to be pathogens. However, a pathogenic role has been shown in some instances. Strains of *Erwinia milletiae* produced β -indolyl acetic acid (a plant hormone), causing galls on some plants in Japan (reviewed by Slade and Tiffin, 1984). Some strains were found to initiate freezing of buffer solutions (which would normally freeze at temperatures below -10°C) at about -4°C . This ice nucleating property plays a critical role in causing frost damage on plants (Kozloff et al., 1983; Lindow et al., 1978). Some strains cause a pink discoloration of canned pineapple (Cho et al., 1980), and others are associated with stalk and leaf necrosis of onion (Hattingh and Walters, 1981). Strains of *Erwinia uredovora* attack the uredia of rust (*Puccinia* spp.) on wheat, oats, and rye (Pon et al., 1954; Dye, 1969).

Strains of the *E. agglomerans* complex have been used for the biological control of plant pathogens (such as *Erwinia amylovora* or *Xanthomonas oryzae*); eliciting their effect either by competition for nutrients, production of acid, or by bacteriocin or phage production (reviewed by Slade and Tiffin, 1984).

E. agglomerans may occur in clinical samples (blood, wounds, sputum, urine), often with dubious clinical significance (von Graevenitz, 1970; Gilardi and Bottone, 1971; Pien et al., 1972). In some cases (von Graevenitz and Palermo, 1980; Cooper-Smith and von Graevenitz, 1978), clinical significance has been demonstrated. In an Ohio hospital, *E. agglomerans* accounted for 4 of 58 episodes of *Enterobacter* bacteremia and one of 42 nosocomial bacteremia (Watanakunakorn and Weber, 1989). In 1970, *E. agglomerans* was implicated in a nationwide outbreak of septicemia caused by contaminated closures on bottles of infusion fluids in the United States. Twenty-five hospitals were involved, with 378 cases and 40 deaths (Maki et al., 1976).

The natural habitat of *E. sakazakii* is unknown. Unless thorough phenotypic descrip-

tions are given in the literature (as yellow-pigmented *E. cloacae*), *E. sakazakii* can hardly be traced in older clinical reports. The yellow pigment production, a distinguishing character (best seen at 25°C), is greatly decreased at the usual incubation temperature of 37°C . Urmenyi and Franklin (1961) reported two cases of neonatal meningitis in England due to yellow-pigmented *E. cloacae*. This organism was isolated from brain tissue and cerebrospinal fluid. Other cases of meningitis have also been described (Jøker et al., 1965; Adamson and Rogers, 1981; Muytjens et al., 1983). Four isolates from wounds and urine were described by Gilardi and Bottone in 1971. This organism was responsible for a necrotizing meningoencephalitis complicated by ventricular compartmentalization and abscess formation (Kleiman et al., 1981). Monroe and Tift (1979) reported neonatal bacteremia in the absence of meningitis.

Enterobacter dissolvens and *E. nimipressuralis* have not been observed in clinical specimens and have only been recovered from environmental sources. *E. dissolvens* was first isolated by Rosen (1922) from diseased corn and is found in rotting cornstalks. *E. nimipressuralis* was described as being the causal agent of wetwood in elm trees (Carter, 1945). These two organisms are very close phenotypically to *E. cloacae* and it is possible that any clinical isolates would have been identified as *E. cloacae*.

E. intermedium was isolated from surface water and unpolluted soil (Izard et al., 1980). Prats et al. (1987) reported the isolation of *E. intermedium* from foot suppurations, blood, feces and bile.

E. amnigenus was mostly isolated from water, but some strains were isolated from clinical specimens such as respiratory tract, wound, or feces (Farmer et al., 1985a).

E. taylora (*E. cancerogenus*) strains were isolated from blood and spinal fluid (Farmer et al., 1985b). Westblom and Coggins (1987) reported the first case of osteomyelitis caused by this species.

E. gergoviae was found in a variety of environmental sources, such as water, cosmetics, and clinical sources, in France, Africa, and the United States (Richard et al., 1976; Brenner et al., 1980). Multiply drug-resistant strains were found in urine samples during an infection outbreak (Richards et al., 1976).

E. asburiae strains were isolated from clinical specimens, mostly urine, respiratory tract, feces, wounds, and blood (Brenner et al., 1986). The clinical significance of this organism is not known.

E. hormaechei was isolated from wounds, sputum, and blood (O'Hara et al., 1989).

Properties Relevant to Pathogenicity for Humans

Histamine decarboxylases are responsible for histamine formation from histidine in food products, thus occasionally resulting in histamine poisoning in humans. Histidine decarboxylase from *E. aerogenes* has been purified and characterized. The enzyme requires pyridoxal-5'-phosphate as a coenzyme and decarboxylates histidine only among the amino acids derived from protein (Guirard and Snell, 1987).

Adhesive properties may be important in the establishment or maintenance of bacterial infections. Adhesins are often also hemagglutinins (HA) and may or may not be located on fimbriae. Most strains of *Enterobacter amnigenus*, *E. cloacae*, and *E. sakazaki* produce a mannose-sensitive hemagglutinin (MS-HA) associated with type 1 fimbriae, i.e., thick, channelled fimbriae of external diameter 7 to 8 nm. These fimbriae can be coated by type 1 fimbrial antiserum against *E. cloacae* 035 but not by type 1 fimbrial antiserum against *Klebsiella pneumoniae* K55/1 (Adegbola and Old, 1983). No other hemagglutinin and fimbrial type has been observed in these species.

Seven of eight *E. gergoviae* strains were found to produce a mannose-resistant *Klebsiella*-like HA (MR/K-HA) agglutinating tanned ox erythrocytes, and they were associated with type 3 fimbriae, i.e., thin, nonchannelled fimbriae of external diameter 4 to 5 nm. These fimbriae can be coated with type 3 fimbrial antiserum against *K. oxytoca* K70/1 (Adegbola and Old, 1983). No other hemagglutinin and fimbrial type has been observed in this species.

Six of eight *E. intermedium* strains produced MS-HA or MR/K-HA or both. MS-HA was associated with type 1 fimbriae that could not be coated by type 1 fimbrial antisera against either *E. cloacae* 035 or *K. pneumoniae* K55/1 (Adegbola and Old, 1983). MR/K-HA produced by *E. intermedium* was associated with type 3 fimbriae that could be coated by type 3 fimbrial antiserum against *Serratia* but not by that against *E. cloacae* or *K. pneumoniae* (Adegbola and Old, 1983; Old and Adegbola, 1984).

All strains of *E. aerogenes* tested produced hemagglutinins (Adegbola and Old, 1983; Adegbola and Old, 1985). Most strains produced a mannose-sensitive hemagglutinin that seemed to be associated with thin (4-nm), nonchannelled fimbriae. These thin fimbriae were antigenically different from the thin fimbriae of other *Enterobacter* and *Klebsiella* species (Adegbola and Old, 1985).

Most strains also produced a nonfimbrial mannose-resistant *Proteus*-like hemagglutinin

(MR/P-HA) which agglutinated untanned guinea pig and horse erythrocytes. A single strain (NCIMB 11460) produced a mannose-resistant *Klebsiella*-like hemagglutinin associated with type-3 fimbriae antigenically similar to *Klebsiella* type-3 fimbriae (Adegbola and Old, 1985).

A single strain of *E. agglomerans* was found to be devoid of hemagglutinin (Adegbola and Old, 1983).

Iron is essential for bacterial growth. In the human body, iron is complexed to carrier molecules such as transferrin (in the serum) or lactoferrin (in milk and other secretions), or sequestered within cells (in heme proteins). When growing under iron-limiting conditions, potentially pathogenic Enterobacteriaceae produce high-affinity systems (siderophores) to solubilize and import the required iron. The iron-chelating compounds produced are mostly of two sorts, phenolates (e.g., enterochelin) and hydroxamates (aerobactin) (Payne, 1988). All strains of *E. cloacae*, *E. aerogenes*, *E. gergoviae*, *E. sakazaki*, and *E. agglomerans* tested by Reissbrodt and Rabsch (1988) produced enterochelin. Some strains of all these species except *E. agglomerans* were found to produce aerobactin. Two of nine strains of *E. agglomerans* produced a hydroxamate compound other than aerobactin (Reissbrodt and Rabsch, 1988). Aerobactin was first isolated from a strain of *E. aerogenes* (then called "*Aerobacter aerogenes*") (Gibson and Magrath, 1969). Aerobactin and cloacin DF13 bind to the same receptor sites located in the outer membrane (Van Tiel-Menkveld et al., 1982). Aerobactin is encoded by a relatively simple genetic system, which has been extensively characterized. Only four genes are required for synthesis of aerobactin (Carbonetti and Williams, 1984). *E. cloacae* harbors a relatively large conjugative plasmid coding for susceptibility to cloacin DF13 as well as for production and uptake of aerobactin (Krone et al., 1985).

The lipopolysaccharide from *E. agglomerans* (commonly found in cotton dust) can bind to the pulmonary lipid-proteinaceous lining material (surfactant) and alter its surface tension properties (DeLucca et al., 1988). This binding in the lung may change the physiological properties of surfactant and be a possible mechanism for the pathogenesis of byssinosis, an occupational respiratory disorder caused by the inhalation of cotton dust (DeLucca et al., 1988).

Antimicrobial Susceptibility

Strains of the *Enterobacter cloacae* complex (including *E. asburiae* and *E. hormaechei*) that have not acquired any resistance determinant are naturally resistant to aminopenicillins (ampi-

cillin) and first-generation cephalosporins (cephalothin). These strains are sensitive to carboxypenicillins (carbenicillin). Among the second-generation cephalosporins, cefamandole is moderately active whereas cefoxitin is not. Third-generation cephalosporins (e.g., cefotaxime, moxalactam) are most active. This natural pattern of resistance is due to the production of an inducible chromosomal cephalosporinase. When a cefoxitin disk is placed in the vicinity of a cefotaxime disk on an antibiotic susceptibility test plate, the wide inhibition zone around the cefotaxime disk is narrower in the vicinity of the cefoxitin disk (Jarlier, 1985).

Acquired resistance arises from the production of a plasmid-determined penicillinase that inactivates carboxypenicillins (carbenicillin) and often ureidopenicillins (mezlocillin) but that does not inactivate third-generation cephalosporins. However, resistance to third-generation cephalosporins (cefotaxime) has been observed, due to the derepression of chromosomal cephalosporinase, or to a plasmid-mediated, extended-spectrum β -lactamase (Jacoby, 1990), or to a reduced expression of outer membrane proteins such as porins (Aggeler et al., 1987). *N*-formimidoyl thienamycin (imipenem) remains active on cefotaxime-resistant strains).

Susceptibility to chloramphenicol, nalidixic acid, and tetracycline differs for *E. cloacae* isolated in different hospitals.

In 1970, all strains of *E. cloacae* were susceptible to gentamicin. During the mid-1970s, plasmid-controlled aminoglycoside resistance spread among Gram-negative bacilli worldwide, and resistance to gentamicin, tobramycin, and (to a lesser extent) amikacin became a concern (John et al., 1982). Resistance of *E. cloacae* to diverse aminoglycoside antibiotics is due to the production of aminoglycoside-modifying enzymes such as aminoglycoside-2''-*O*-nucleotidyltransferase, aminoglycoside-3'-*O*-phosphotransferase, aminoglycoside-3-*N*-acetyltransferase, or aminoglycoside-6'-*N*-acetyltransferase (John et al., 1982).

Antibiotic susceptibility of *E. aerogenes* is similar to that of *E. cloacae*. Most strains of *E. aerogenes* are naturally resistant to ampicillin, cephalothin, and cefoxitin, and susceptible to carbenicillin.

Generally *E. sakazakii* is susceptible to ampicillin, carbenicillin, amikacin, cefamandole, cefoxitin, aminoglycosides, chloramphenicol, and nalidixic acid, but 87% of the strains are resistant to cephalothin (Farmer et al., 1980). Compared to *E. cloacae*, *E. sakazakii* strains exhibit larger zones of inhibition around ampicillin and cephalothin antibiotic disks, a property which also helps to differentiate the latter species from *E. cloacae*.

Most *E. agglomerans* strains are naturally resistant to ampicillin and cephalothin and susceptible to many antibiotics including aminoglycosides, carbenicillin, cefamandole, cefuroxime, and cefoxitin. Resistance to carbenicillin may occur.

E. gergoviae strains are susceptible to antibiotics but strains isolated from urinary tract infection were found to be resistant to ampicillin and cephalothin (Richard et al., 1976).

Strains of *E. taylorae* (= *E. cancerogenus*) were generally susceptible to colistin, nalidixic acid, sulfadiazine, gentamycin, kanamycin, chloramphenicol, tetracycline, cefotaxime, cefoperazone, piperacillin, ticarcillin, tobramycin, and gentamicin, and resistant to cephalothin and cefadroxil. Susceptibility to ampicillin and carbenicillin varies among strains (Westblom and Coggins, 1987).

Except for ampicillin, cephalothin, and cefoxitin, *E. intermedium* is susceptible to all the antimicrobial agents generally active against Gram-negative rods.

Biotechnology

Enzymes

Diacetyl is an undesirable flavor component in young beer. α -Acetolactate (an intermediate of the isoleucine-valine pathway) is converted to diacetyl solely by non-enzyme-catalyzed oxidative decarboxylation, and then it is reduced, during the maturation process, to acetoin by diacetylreductase. α -Acetolactate can be converted directly to acetoin by an α -acetolactate decarboxylase which is found in several *Enterobacter* species. The α -acetolactate decarboxylase gene of *E. aerogenes* has been cloned (Sone et al., 1987) and introduced by transformation into brewer's yeast. The diacetyl concentration in wort fermented by the recombinant yeast was lower than that in wort fermented by the parental strain (Sone et al., 1988).

Chromate (hexavalent chromium) is a strong oxidant that is toxic and mutagenic in bacterial test systems. A chromate-resistant strain of *E. cloacae* that reduces chromate to chromium hydroxide (insoluble and less toxic) under anaerobic conditions has been isolated and characterized (Wang et al., 1989).

Nitrogen-Fixing Species of *Enterobacter*

Nitrogen-fixing *Enterobacter* species have been occasionally reported (Barroquio and Watanabe, 1981) but the confusion regarding the taxonomy of *E. cloacae* and *E. agglomerans* render published identifications as provisional.

The specific nitrogenase activity of *E. agglomerans* isolated from paper-mill-process water was

10 μmol of acetylene per mg protein per h (Neilson and Sparell, 1976) and that reported for *E. agglomerans* isolated from grass root was only 1.6 μmol of acetylene per mg protein per h (Haahtela et al., 1983).

Nitrogen-fixing *E. cloacae* have been isolated from the roots of dryland and wetland rice (Ladha et al., 1983). The nitrogen-fixing *E. cloacae* strains isolated by Bally et al. (1983) were found to belong in *E. cloacae* genomic group 5 (P.A.D. Grimont, unpublished observations).

Isolation

Media used in the isolation of *Enterobacter* species are similar to those used for other Enterobacteriaceae. There are no selective media for *Enterobacter* species. The requirements of a selective medium are 1) a precise and stable delineation of the genus (or species, if the medium is to be species specific); 2) known common properties within the genus (or species) which are uncommon outside the genus (or species); and 3) a clinical, public health, or special need for such selective medium. Due to pending changes in the delineation of the genus *Enterobacter* (e.g., exclusion of the *E. agglomerans* complex) and of the species *E. cloacae* and *E. agglomerans*, conditions 1 and 2 are not met. Except for some epidemiological studies, the selective isolation of *Enterobacter* spp. is rarely necessary since the presence of *Enterobacter* spp. in pluribacterial habitats (feces, throat, skin) is clinically meaningless. The public health significance of *Enterobacter* spp. in water or foods is uncertain. Isolation of *Enterobacter* spp. from clinical specimens is done either by direct plating on blood agar, tryptic soy agar, or nutrient agar (e.g., pus, urine) or by plating after prior growth in tryptic soy broth or nutrient broth (blood, pus, cerebrospinal fluid).

On nutrient agar, *E. cloacae*, *E. aerogenes*, *E. gergoviae*, *E. amnigenus*, *E. nimipressuralis*, *E. intermedium*, or aerogenic *E. agglomerans* strains (*Leclercia* spp.) form colonies that are round, 2–3 mm in diameter, and slightly iridescent or flat with irregular edges (Richard, 1984). Aerogenic *E. agglomerans* strains can form yellow-pigmented colonies. Anaerogenic *E. agglomerans* strains (*Pantoea* spp.) form either mucoid colonies, or smooth and irregularly round colonies, or rough and wrinkled colonies, which are difficult to remove with a platinum wire. These colonies are often yellow pigmented. *E. sakazakii* strains form bright yellow colonies at 25°C or pale yellow colonies at 37°C, 1 to 3 mm in diameter. These colonies are smooth, mucoid, or dry (Farmer et al., 1980).

Differential media which are not inhibitory for the Enterobacteriaceae are often used. These are bromothymol blue-lactose agar, phenol red-lactose agar, Drigalski lactose agar, eosin methylene blue agar, or MacConkey agar. It should be remembered that some strains of a species known to produce acid from lactose may fail to do so. A differential medium, lysine-ornithine-mannitol agar containing vancomycin, was proposed for the isolation of *Enterobacter agglomerans*. It yields colorless colonies from mannitol-negative strains, yellow colonies from mannitol-positive, ornithine- and lysine-decarboxylase negative strains, and greenish-blue colonies from mannitol-positive strains producing one or both decarboxylases (Bucher and von Graevenitz, 1982).

Identification

The normal methods used for the identification of *Enterobacter* species and other Enterobacteriaceae can be found in Ewing (1986) and Farmer et al. (1980). However, other tests are extremely useful in enterobacterial taxonomy. These include carbon source utilization tests, glucose oxidation (in the presence or in the absence of added pyrroloquinoline quinone), gluconate and 2-ketogluconate dehydrogenase tests, and tetrathionate reductase and β -xylosidase tests. These tests and a modified Voges-Proskauer test are described in detail in The Genus *Serratia* from the second edition.

Conditions of Incubation

Best results are obtained when *Enterobacter* cultures are incubated at 30°C. At 37°C, yellow pigmentation of *E. sakazakii* or *E. agglomerans* may be weak.

Identification of *Enterobacter* at the Genus Level

The impending changes in the delineation of the genus *Enterobacter* prevent any stable definition of the genus. Presently, most *Enterobacter* species and biogroups are positive for the Voges-Proskauer and Simmons citrate tests, are motile, produce acid from D-glucose, D-mannitol, salicin, L-arabinose, L-rhamnose, D-xylose, trehalose, D-cellobiose, and maltose; hydrolyze *o*-nitrophenyl- β -D-galactoside, reduce nitrate, and oxidize D-glucose to D-gluconate in the presence of pyrroloquinoline quinone. All *Enterobacter* species (except some *E. agglomerans* genomic groups) produce gas from glucose. The following substrates are utilized by most strains: *N*-acetyl-D-glucosamine, D-alanine, L-alanine, L-arabinose, L-aspartate, D-cellobiose, citrate,

D-fructose, fumarate, D-galactose, D-galacturonate, gentiobiose, D-gluconate, D-glucosamine, D-glucose, D-glucuronate, L-glutamate, DL-glycerate, glycerol, 2-ketogluconate, DL-lactate, lactose, maltose, maltotriose, D-mannitol, D-mannose, 1-O-methyl- β -D-galactoside, 1-O-methyl- β -D-glucoside, L-rhamnose, D-ribose, L-serine, succinate, D-trehalose, and D-xylose.

Most *Enterobacter* species or biogroups are negative for the following tests: H₂S production from thiosulfate, phenylalanine deaminase, tetrathionate reduction, tributyrin or corn oil hydrolysis, β -glucuronidase, and 2-ketogluconate dehydrogenase. Most strains cannot utilize the following substrates as sole carbon and energy sources: caprate, caprylate, ethanolamine, glutarate, itaconate, D-melezitose, 3-phenylpropionate, propionate, and L-sorbose.

Identification of *Enterobacter* at the Species Level

The characteristics that are most useful for the identification of seven *Enterobacter* species and the *E. cloacae* and *E. agglomerans* complexes are given in Table 2 and detailed characteristics are given in Tables 3, 4, 5. Results of carbon sources utilization tests given in Tables 2–5 are mostly unpublished observations.

E. aerogenes and *E. gergoviae* possess gluconate dehydrogenase and lysine decarboxylase, produce acid from D-arabitol, and utilize D-arabitol and histamine, and most strains utilize gentisate, 3-hydroxybenzoate, and tricarballoylate. *E. aerogenes* can be separated from *E. gergoviae*

by urea hydrolysis, β -xylosidase test, acid production from adonitol, methyl- α -D-glucoside, and sorbitol; and by utilization of *trans*-aconitate, adonitol, *m*-coumarate, maltitol, mucate, palatinose, D-saccharate, and D-sorbitol.

E. intermedium is positive for ornithine decarboxylase and acid production from dulcitol, and utilization of dulcitol, 4-hydroxybenzoate, 5-ketogluconate, protocatechuate, quinate, D-sorbitol, and D-tagatose. It is negative for lysine decarboxylase and arginine dihydrolase.

E. sakazakii, *E. cancerogenus* (= *E. taylora*), *E. amnigenus*, *E. nimipressuralis*, and the *E. cloacae* complex are positive for arginine dihydrolase and ornithine decarboxylase, and negative for lysine decarboxylase and gluconate dehydrogenase. These species can be separated by the following tests: yellow pigment production, glucose dehydrogenase (without added pyrroloquinoline quinone), β -xylosidase, acid production from D-raffinose, D-sorbitol, and sucrose, and utilization of L-fucose, D-lyxose, maltitol, D-melibiose, 3-O-methyl-D-glucose, palatinose, phenylacetate, putrescine, D-sorbitol, and sucrose. In addition, an α -glucosidase test was proposed to separate *E. sakazakii* (α -glucosidase positive) from other *Enterobacter* species (α -glucosidase negative) (Muytjens et al., 1984).

The phenotypic properties of genomic groups and subgroups within the *E. cloacae* complex are given in Table 3. Genomic group 1 is presently only represented by three strains, including the type strains of *E. cloacae* and *E. dissolvens*. This group is difficult to differentiate phenotypically

3-Methylglucose	+	–	+	–	–	+	–

Symbols: +, all strains positive in 1–2 days (carbon source utilization tests) or in one day (other tests); (+), all strains positive in 1–4 days; –, all strains negative in 4 days; v, positive or negative in 1–4 days.

^aFive strains representing *E. hormaechei* (including the type strain) and received from the Centers for Disease Control corresponded to biogroup 3a.

from genomic group 2. Genomic group 3 (containing the type strain of *E. hormaechei*) is unique in oxidizing D-glucose to D-gluconate without added pyrroloquinoline quinone. Phenotypic identification of genomic group 4 is easier at the subgroup level. Subgroups 4a (containing the type strain of *E. asburiae*), 4b, and 4c are differentiated by utilization of dulcitol, D-melibiose, phenylacetate, putrescine, and L-rhamnose. Genomic group 5 utilizes dulcitol, phenylacetate, and L-rhamnose, and does not utilize putrescine. Genomic groups 4 and 5 hydrolyze esculin rapidly.

The diversity of biogroups within *E. cloacae* genomic group 3 is shown in Table 4. Strains presently identified as *E. hormaechei* belong in biogroup 3a. These strains are negative for utilization of D-melibiose, D-raffinose, α -methyl-D-galactoside, sorbitol, and adonitol. Most clinical isolates recovered from blood and received as *E. cloacae* from hospitals in Paris corresponded to genomic group 3, biogroups 3b, 3d and 3f.

Enterobacter strains that are negative in lysine and ornithine decarboxylases and arginine dihydrolase, whether or not they produce a yellow pigment, are currently identified as *E. agglomer-*

Table 5. Differential phenotypic characteristics of genomic species (I to XIII) within the *Enterobacter agglomerans* complex.

ans. Several biotypes were described (Ewing and Fife, 1972). The differential phenotypic properties of strains belonging to the major genomic groups of Brenner et al. (1984) are shown in Table 5 (P.A.D. Grimont, E. Ageron, and D.J. Brenner, unpublished observations). DNA groups XIII, III, VI, and XI correspond respectively to *Pantoea agglomerans*, *P. dispersa*, “*Erwinia*” *ananas*, and *Leclercia adecarboxylata*. Anaerogenic groups XIII, V, III, I, II, IV, and VI are able to oxidize D-glucose to D-gluconate (glucose dehydrogenase activity) without added pyrroloquinoline quinone, and D-gluconate to 2-ketogluconate (gluconate dehydrogenase activity). In addition, these groups cannot utilize phenylacetate, and most strains can utilize *myo*-inositol. These tests could define the genus *Pantoea*.

Genomic groups XI and VII are very similar (indol produced, malonate test positive, utilization of phenylacetate) although only group XI (*Leclercia adecarboxylata*) is aerogenic.

Table 5 is oversimplified since a number of strains that did not fall into DNA groups I to XIII (Brenner et al., 1984) are not included.

Serotyping of *Enterobacter cloacae*

Sakazaki and Namioka (1960) distinguished 53 O and 56 H antigens in agglutination tests, and 170 isolates were distributed in 79 serotypes. Bacterial suspensions had to be boiled to be agglutinated by O antisera. Unfortunately, epidemiological investigations using this serotyping scheme have not been reported.

Gaston et al. (1983) devised a serotyping scheme based on heat-stable somatic (O) antigens. A total of 28 antisera including 11 absorbed sera were used, thus defining 28 O serogroups. Of 300 clinical isolates from 66 hospitals, 78% were typable, 11% were not agglutinated by any of the sera, and 11% were autoagglutinable in saline.

Capsular Typing of *Enterobacter aerogenes*

About 81% of *E. aerogenes* strains are surrounded by a thin capsule antigenically related to *Klebsiella* capsular antigens. Thus, *Klebsiella* K antisera can be used to type strains of *E. aero-*

genes. The following antisera reacted with *E. aerogenes* capsular antigens: K4, K4+59, K11, K26, K42, K59, and K68 (Richard, 1977). Strains of *E. aerogenes* are not agglutinated by *E. cloacae* O antisera (Gaston et al., 1989).

Serotyping of *Enterobacter agglomerans*

The principal antigens in most strains of *E. agglomerans* (*Erwinia herbicola*) are uncharged capsular polysaccharides. These antigens are not removed from the cells by heating at 100°C for 30 min (Slade and Tiffin, 1984). Most members of the "herbicola group" are motile, but there is no report on the antigenic structure of the flagella (Slade and Tiffin, 1984), and most strains produce antigenically similar, high-molecular-weight, acidic polysaccharides.

Two schemes have been proposed for "*E. herbicola*." Muraschi et al. (1965) used immunodiffusion and antigens extracted by aqueous ether. They classified 55 isolates into seven serotypes, although "some cultures were mixtures of more than one serotype." A second scheme was established by Slade (cited by Slade and Tiffin, 1984), using laboratory strains. This scheme has not been used to type new isolates.

Bacteriocin Typing of *Enterobacter cloacae*

Three different schemes have been developed for typing *E. cloacae* strains by susceptibility to bacteriocins:

1. Freitag and Friedrich (1981) were able to type 51 of 65 strains (78%), which were assigned to 23 bacteriocin types designated A through X (type Y contained nontypable isolates).

2. Traub et al. (1982) found 9% of 256 *E. cloacae* isolates to be bacteriocinogenic. Bacteriocins were produced by 16 strains after induction by mitomycin. A total of 308 isolates from various clinical sources were studied and 79% fell into 52 bacteriocin types leaving 21.4% of the isolates untypable.

3. Reference is not an exact match Bauernfeind and Petermüller (1984) found 132 of 149 isolates to produce bacteriocins. With a set of eight bacteriocin-producing strains, typability of 134 clinical isolates was 96.3%. A total of 44 different bacteriocin types could be distinguished. Only 11 (8.2%) of the isolates fell into the largest bacteriocin type. Other species of *Enterobacter* (*E. agglomerans* and *E. aerogenes*) were also typable by the selected *E. cloacae* bacteriocins.

Phage Typing of *Enterobacter cloacae*

From sewage Gaston (1987a) isolated 76 phages active against *E. cloacae*. Of these, 26 phages

were selected after numerical taxonomy analysis of their reaction patterns on 92 *E. cloacae* strains. This system has been tried on 384 isolates and 94% of these isolates were susceptible to at least one phage. A total of 325 different phage susceptibility patterns were observed. Reproducibility of patterns was 100% when duplicate testing was on the same day, and only 40% when duplicate testing was done after 18 months (Gaston, 1987b).

The Genus *Hafnia*

MEGAN E. MCBEE AND DAVID B. SCHAUER

Introduction

The genus *Hafnia* was recognized by Møller (1954) while studying amino acid decarboxylase patterns among Enterobacteriaceae. Members of this taxon are Gram-negative, facultatively anaerobic rods that are typically methyl red and Voges-Proskauer positive, positive for lysine and ornithine decarboxylase, and negative for arginine dihydrolase. The taxonomic position of these organisms has been the subject of some controversy, and over the years they have been referred to as *Bacillus asiaticus* (cited by Ewing and Fife, 1968), *Bacterium cadaveria* (Gale and Epps, 1943), *Aerobacter* species biotype 32011 (Stuart et al., 1943b), *Enterobacter alvei* (Sakazaki, 1961), *Enterobacter aerogenes* subsp. *hafniae* (Ewing, 1963), and *Enterobacter hafniae* (Ewing and Fife, 1968). However, DNA hybridization studies have shown that these organisms are distinct from *Enterobacter* (Steigerwalt et al., 1976), and *Hafnia alvei* (the only recognized species of the genus) is a legitimate taxon.

Barbe described two *H. alvei* biotypes, which can be distinguished by hydrolysis of arbutin and esculin and fermentation of salicin and D-arabinose (cited in Introduction to the Family Enterobacteriaceae in the second edition). Janda et al. (2002) subsequently identified isolates that fell into two additional biogroups (Table 1). These authors reported that isolates belonging to biogroup 2 were less common than isolates belonging to biogroup 1 and that isolates belonging to biogroups 3 and 4 were rare (Janda et al., 2002). Both DNA relatedness (Steigerwalt et al., 1976) and 16S ribosomal RNA gene sequencing (Janda et al., 2002) indicate that there are at least two distinct genomospecies of *H. alvei*. Because the genomospecies cannot be clearly distinguished by phenotypic characteristics, they remain classified as a single heterogeneous species. It has been suggested that genomospecies 1, which includes the majority of isolates as well as the type strain (ATCC 13337), should be considered *H. alvei* sensu stricto (Janda et al., 2002).

Habitat

Hafnia alvei can be isolated from feces in apparently healthy individuals, as well as from mammals, birds, reptiles and fish. It can also be isolated from a range of environmental sources, including soil, water and sewage, as well as from food. Early studies incriminated biotype 32011 of paracolon bacteria, now classified as *H. alvei*, as a cause of diarrhea (cited in The Genus *Hafnia* in the second edition). Diarrhea-associated isolates, more recently identified as *H. alvei* and shown to possess a locus of enterocyte effacement (LEE) pathogenicity island and to produce attaching and effacing lesions (Albert et al., 1991; Albert et al., 1992), were subsequently found to be distinct from true *H. alvei* (Ridell et al., 1995; Ismaili et al., 1996; Janda et al., 1999). These strains are now classified as *Escherichia albertii* (Abbott et al., 2003; Huys et al., 2003). Thus, the role of *H. alvei* as a primary cause of gastroenteritis and diarrheal disease remains uncertain.

The main clinical significance of *H. alvei* is as a rare cause of opportunistic infections, particularly in compromised hosts. *Hafnia alvei* has been isolated from urine, blood, wound and abscess exudate, and sputum, in addition to stool specimens. *Hafnia alvei* has been implicated as a cause of septicemia, endocarditis, meningitis, peritonitis, pneumonia, urinary tract infections, liver abscesses, and cholangitis (reviewed by Englund [1969], Conte et al. [1996], Günthard and Pennekamp [1996], Barry et al. [1997], and Ramos and Damaso [2000]). Because *H. alvei* is often found in mixed cultures, it can be difficult to ascribe unequivocal clinical significance to the organism. *Hafnia alvei* causes both nosocomial and community acquired infections. The vast majority of patients with *H. alvei* infections have underlying illnesses.

Isolation

As reviewed in The Genus *Hafnia* in the second edition, there are no specific media for the isola-

tion of *H. alvei*, but media commonly employed for isolating other Enterobacteriaceae can be used. In the absence of a specific enrichment broth, selenite and tetrathionate are suitable for the recovery of some *H. alvei* strains, but other strains will not grow in these media. Some strains will grow at 4°C, and care must be taken to distinguish these isolates from *Yersinia* species if cold enrichment is used. Plating media, such as eosin methylene blue (EMB), MacConkey lactose, xylose-lysine-deoxycholate (XLD), and Hektoen, have been used to isolate *H. alvei*. Because it does not ferment lactose, *H. alvei* forms colorless colonies on these media, and care should be taken to distinguish it from *Salmonella* species. Highly selective media, such as *Salmonella-Shigella* (SS), can inhibit the growth of up to 25% of *H. alvei* strains (The Genus *Hafnia* in the second edition). Growth on less inhibitory media yields smooth, translucent colonies with complete edges. *Hafnia alvei* rarely produces mucoid colonies. Sakazaki recommended the use of MacConkey agar containing 1% sorbitol (SMAC) to isolate *H. alvei* (cited in The Genus *Hafnia* in the second edition). Because it does not ferment sorbitol, its colorless colonies can be distinguished from Enterobacteriaceae that do ferment this sugar, including many strains of *E. coli*, *Citrobacter*, *Klebsiella*, *Enterobacter* and *Serratia*. Enterohemorrhagic *E. coli* O157:H7 does not ferment sorbitol and is often isolated on SMAC, therefore fecal isolates of *H. alvei* must be distinguished from *E. coli* O157:H7.

Identification

Conforming to the definition of the family Enterobacteriaceae, members of the genus *Hafnia* are Gram-negative, facultatively anaerobic rods, and typically motile by peritrichous flagella (see Introduction to the Family Enterobacteriaceae in the second edition). Isolates of *H. alvei* are typically not encapsulated. Identification is most commonly based on patterns of biochemical reactions (Table 2). Sakazaki and Tamura (The Genus *Hafnia* in the second edition) indicate

From Holt et al. (1994).

that the variable methyl red and Voges-Proskauer reactions seen with *H. alvei* at 35°C are consistently negative and positive, respectively, when carried out at 22–25°C. Likewise, citrate utilization on Simmons' citrate media is negative at 35°C but often delayed positive (3–4 days) at 22–25°C. These authors also report that motility is also increased when cultures are incubated at room temperature.

In the clinical laboratory, *H. alvei* must be differentiated from members of the closely related genera *Enterobacter* and *Serratia*. This can be accomplished with selected biochemical tests (Table 3). *Hafnia alvei* is negative (or delayed positive) for citrate utilization, while *Enterobacter* and *Serratia* are positive. *Hafnia alvei* is

^aAssays performed at 36 ± 1°C, except gelatin hydrolysis (22°C) and DNase (25°C).

^b*Enterobacter* exceptions are for lysine decarboxylase (*E. gergoviae*), gelatin hydrolysis (*E. nimipressuralis*), and sucrose fermentation (*E. amnigenus* biogroup 2, *E. nimipressuralis*, and *E. taylorae*). *Serratia* exceptions are for arginine dihydrolase (*S. grimesii*), gelatin hydrolysis and DNase (*S. fonticola*), lipase (*S. entomophila* and *S. fonticola*), and sucrose fermentation (*S. fonticola* and *S. odorifera* biogroup 2).

From Holt et al. (1994).

lysine decarboxylase positive, while *Enterobacter* species, with the exception of *Enterobacter gergoviae*, are negative. *Hafnia alvei* is negative for DNase activity, gelatin hydrolysis, and lipase activity, while *Serratia* species are typically positive for these tests, with the exception of *Serratia fonticola*. Some strains of *Serratia entomophila* are also negative for lipase.

Escherichia albertii in Bangladeshi children with diarrhea was initially misidentified as *H. alvei* (Albert et al., 1991). Abbott et al. (2003) found that 4 of 5 *E. albertii* strains were identified as *H. alvei* using API 20E strips (bioMérieux, Inc.), albeit at low probabilities, and 3 of 5 of these strains were identified as *H. alvei* using Vitek GNI Plus (bioMérieux, Inc.). The weak to moderate L-proline aminopeptidase activity noted in *E. albertii* strains is a useful test to distinguish them from *H. alvei*. *Hafnia alvei* exhibit strong L-proline aminopeptidase activity within 30 min to 2 h (Abbott et al., 2003).

Perhaps the most reliable method for identification of *H. alvei* is the *Hafnia*-specific bacteriophage 1672 described by Guinée and Valkenburg (1968). All *H. alvei* strains are lysed by the phage but not strains of *Enterobacter*, *Klebsiella*, *Citrobacter*, *Serratia* or *Salmonella* (cited by in The Genus *Hafnia* in the second edition). *Escherichia albertii* strains are also not lysed by *Hafnia* phage 1672 (Janda et al., 1999).

Identification of *H. alvei* with Phage 1672 (Guinée and Valkenburg, 1968).

The specific phage 1672 was isolated from surface water with *H. alvei* strain 1672 as the propagating bacterium.

Surface inoculate a well-dried nutrient agar plate with a fresh broth culture of the strain to be tested. After decantation, allow the plate to dry at room temperature for 15 min. Spot a drop of the undiluted phage 1672 on the plate with a Pasteur pipette, and allow the plate to dry again. Read after 16–20 h of incubation at 35°C. Clear plaques with a diameter of 1–2 mm are produced. Obtain the phage preparation (ca. 10⁹ plaque-forming units per ml) after the usual purification. The phage is not inactivated by heating at 60°C for 30 min.

Stuart and Rustigian (1943a) characterized biotype 32011 of paracolon bacteria, now classified as *H. alvei*, dividing it into 8 serovars. Subsequent studies identified additional O and H serogroups (Deacon, 1952; Eveland and Faber, 1953), but some of these organisms are now recognized to be species other than *H. alvei* (cited in The Genus *Hafnia* in the second edition). More recently, chemical studies have elucidated the structural nature of the lipopolysaccharide (LPS) and O antigen of several *H. alvei* strains (reviewed by Romanowska, 2000). Although serotyping currently has little practical application for identification of *H. alvei*, it should be noted that some isolates cross-react with O antisera of *Salmonella* species and *E. coli* (The Genus *Hafnia* in the second edition).

Antibiotic Resistance

The majority of *H. alvei* strains are sensitive to carbenicillin, streptomycin, gentamycin, kanamycin, chloramphenicol, tetracycline, polymyxin B and nalidixic acid, but resistant to ampicillin and cephalothin (The Genus *Hafnia* in the sec-

ond edition). Günthard and Pennekamp (1996) found *H. alvei* isolates from patients with community acquired and nosocomial infections were all sensitive to ciprofloxacin and imipenem. Approximately 90% of the isolates were also sensitive to the third generation cephalosporins (ceftriaxone and ceftazidime). With a more limited number of isolates, Ramos and Damaso (2000) reported some resistance to amoxicillin/clavulanic acid and first generation cephalosporins but also found that all isolates were sensitive to aminoglycosides, ciprofloxacin, imipenem, and the third generation cephalosporin cefotaxime.

The Genus *Serratia*

FRANCINE GRIMONT AND PATRICK A. D. GRIMONT

The genus *Serratia* a member of the Enterobacteriaceae (see Introduction to the Family Enterobacteriaceae from the second edition.), is comprised of a group of bacteria that are related both phenotypically and by DNA sequence. The type species of the genus is *Serratia marcescens*. Some species and biotypes of *Serratia* produce a nondiffusible red pigment, prodigiosin, or 2-methyl-3-amyl-6-methoxyprodigiosene (Williams and Qadri, 1980). The multiplication of red-pigmented *Serratia* was incriminated in the appearance of bloodlike spots (e.g., on bread, consecrated wafers [sacramental Hosts], and polenta) with rather disastrous sociological consequences. In this context, several scholars have traced the history of the genus *Serratia* back to antiquity (Gaughran, 1969; Harrison, 1924; Reid, 1936). However, several bacterial species outside the genus *Serratia* produce prodigiosin or prodigiosin-like pigments (Williams and Qadri, 1980) or many other kinds of red pigments, and the identity of microorganisms involved in these striking phenomena can only be surmised.

Bizio (1823) named the red-pigmented microorganism he observed on polenta *Serratia marcescens*. Ehrenberg (1848) named a motile bacterium isolated from red spots on food “*Monas prodigiosa*.” No cultures of these organisms were preserved, but the name *Serratia marcescens* was preferred over the name “*Erythrobacillus pyosepticus*”—a culture of which was preserved as ATCC 275 (Fortineau, 1904)—by Breed and Breed (1924, 1927) and by the editors of *Bergey's Manual of Determinative Bacteriology* (Bergey et al., 1923). The name *Serratia marcescens* is now universally accepted, and a neotype strain has been designated (Martinec and Kocur, 1961a).

At the start of this century, more than 76 nomenspecies had been described with red or pink pigmentation (Hefferan, 1904), and 23 *Serratia* species were listed in the first edition of *Bergey's Manual* (Bergey et al., 1923). This number progressively decreased to five in the fifth edition of *Bergey's Manual* (Breed et al., 1957), and later to one species: *S. marcescens* (Ewing et al., 1959; Martinec and Kocur, 1960, 1961a, 1961b, 1961c, 1961d). The only *Serratia* species recognized in the eighth edition of *Bergey's Manual* was *S. marcescens* (Sakazaki, 1974). Then, new objective approaches, such as numerical taxonomy and DNA relatedness applied to strains recovered from diverse habitats, delineated an increasing number of species in the genus *Serratia*. Five and seven species, respectively, were mentioned in the first edition of *The Prokaryotes* (Grimont and Grimont, 1981) and in *Bergey's Manual of Systematic Bacteriology* (Grimont and Grimont, 1984). Ten species are presently known to belong in the genus *Serratia*. These species (and synonyms) are:

1. *Serratia marcescens* Bizio 1823: “Typical” *S. marcescens* (Colwell and Mandel, 1965; Ewing et al., 1959; Martinec and

Kocur, 1961a); *Serratia* pattern 1 (Fulton et al., 1959); *Serratia* biotype 1 (Bascomb et al., 1971); phenon A (Grimont and Dulong de Rosnay, 1972; Grimont et al., 1977b); *S. marcescens* DNA hybridization group (Steigerwalt et al., 1976). The neotype strain is ATCC 13880, CDC 813-60, Grimont 504, and CCM 303 (Martinec and Kocur, 1961a). The name appeared in the *Approved Lists of Bacterial Names* (Skerman et al., 1980). The type strains of “*Bacillus indicus*” (Eisenberg, 1886), “*Erythrobacillus pyosepticus*” (Fortineau, 1904), “*Bacillus sphingidis*” (White, 1923a), and “*Serratia anolium*” (Duran-Reynals and Clausen, 1937) are all referable to the taxonomic entity now known as *S. marcescens*. Strains labeled “*S. marcescens* subsp. *kiliensis*” according to Ewing et al. 1962 were Voges-Proskauer-negative variants of *S. marcescens*.

2. *Serratia liquefaciens* (Grimes and Hennerty 1931) Bascomb et al. 1971: “*Aerobacter liquefaciens*” Grimes and Hennerty 1931; “*Aerobacter lipolyticus*” Grimes 1961; *Enterobacter liquefaciens* (Grimes and Hennerty, 1931) Ewing 1963; phenon Clab (Grimont et al., 1977b); *Serratia liquefaciens* sensu stricto (Grimont et al., 1982a, 1982b). The type strain is ATCC 27592, CDC 1284-57, and Grimont 866. The name appeared in the *Approved Lists of Bacterial Names* (Skerman et al., 1980). It should be mentioned that the strain considered to be the type strain of “*Aerobacter liquefaciens*,” or of “*Aerobacter lipolyticus*” by Grimes (1961), was ATCC 14460 (now the type strain of *S. grimesii*). Since this strain was considered atypical, another strain (ATCC 27592) was given as the type strain in the *Approved Lists*.

3. *Serratia proteamaculans* (Paine and Stansfield 1919) Grimont et al. 1978b: *S. proteamaculans* sensu stricto (Grimont et al., 1982a, 1982b). The type strain is ATCC 19323, Grimont 3630, ICPB XP176, and NCPPB 245. The name appeared in the *Approved Lists of Bacterial Names* (Skerman et al., 1980). *S. proteamaculans* and *S. liquefaciens* were thought to be synonymous on the basis of DNA relatedness (Grimont et al., 1978b). However, subsequent observation of significant thermal instability of DNA hybrid fragments supported the separation of both species (Grimont et al., 1982a).

Biogroup RQ was named *S. proteamaculans* subspecies *quinovora* (Grimont et al., 1982a, 1982b) with strain Grimont 4364, CIP 8195, and ATCC 33765 as the type strain.

4. *Serratia grimesii* Grimont et al. 1982a, 1982b: phenon Cld (Grimont et al., 1977b); *S. liquefaciens* hybridization group (Steigerwalt et al., 1976). The type strain is ATCC 14460 and Grimont 503. This strain had been considered as the type strain of *S. liquefaciens* prior to the publication of the *Approved Lists*.

5. *Serratia plymuthica* (Lehmann and Neumann 1896) Breed et al. 1948: “*Bacterium plymuthicum*” Lehmann and

Neumann 1896; excluded from the genus *Serratia* (Ewing et al., 1959); “atypical” *S. marcescens* (Colwell and Mandel, 1965); “*S. marcescens* var. *kiliensis*” according to Martinec and Kocur (1961d) (not Ewing et al., 1962); *Serratia* III (Mandel and Rownd, 1964); *Serratia* pattern 2 (Fulton et al., 1959); atypical *S. rubidaea* (Ewing et al., 1972, 1973); and phenon C2 (Grimont et al., 1977b). The type strain is Grimont 510, CCM 640, and ATCC 183. The type strains of “*Bacterium kiliense*” reference is not an exact match Lehmann and Neumann 1986 and “*Serratia esseyana*” Combe 1933 are *S. plymuthica*.

6. *Serratia rubidaea* Stapp 1940 (Ewing et al., 1973): “*Bacterium rubidaeum*” Stapp 1940; “*Prodigiosus*” VIII (Hefferan 1904); *S. marinorubra* ZoBell and Upham 1944; *Serratia* biotype 2 (Bascomb et al., 1971); phenon B (Grimont and Dulong de Rosnay, 1972; Grimont et al., 1977b); *S. rubidaea* DNA hybridization group (Steigerwalt et al., 1976). The name appeared in the *Approved Lists of Bacterial Names* (Skerman et al., 1980). The type strain (neotype) is ATCC 27593, CDC 2199-72, and Grimont 864. The former type strain (holotype) of *S. marinorubra* was NCTC 10912, ATCC 27614, and Grimont 288. However, the *Approved Lists of Bacterial Names* (Skerman et al., 1980) listed *S. marinorubra* with ATCC 27593 as the type strain. Thus, both names (*S. rubidaea* and *S. marinorubra*) were made objective synonyms and the name *S. rubidaea* has priority. Three subspecies can be delineated: *S. rubidaea* subsp. *rubidaea*, *S. rubidaea* subsp. *burdigalensis*, and *S. rubidaea* subsp. *colindalensis* (Grimont et al., manuscript in preparation).

7. *Serratia odorifera* Grimont et al. 1978a: Strains similar to the unclustered *Serratia* strain 38 (Grimont and Dulong de Rosnay, 1972; Grimont et al., 1977b). The type strain is ATCC 33077, CDC 1979-77, Grimont 1073, ICPB 3995, and NCTC 11214. The name appeared in the *Approved Lists of Bacterial Names* (Skerman et al., 1980).

8. *Serratia ficaria* Grimont et al. 1979c: the type strain is ATCC 33105, Grimont 4024, CIP 79.23, and ICPB 4050.

9. *Serratia entomophila* Grimont et al. 1988: the type strain is ATCC 43705, Jackson A1, and CIP 102919.

10. *Serratia fonticola* Gavini et al. 1979: Lysine-positive *Citrobacter*-like (Steigerwalt et al., 1976). The type strain is ATCC 29844, CUETM 77.165, Grimont 4011, and CIP 78.64. The name appeared in the *Approved Lists of Bacterial Names* (Skerman et al., 1980).

The inclusion of the genus *Serratia* in the tribe Klebsiellae is no longer tenable. Studies on DNA relatedness, immunological cross-reaction between isofunctional enzymes, and the physical properties, regulation, and amino acid sequences of enzymes have all shown the genus *Serratia* to be consistently different from the group composed of the genera *Escherichia*, *Shigella*, *Salmonella*, *Citrobacter*, *Klebsiella*, and *Enterobacter* (reviewed by Grimont and Grimont, 1978a).

Until the late 1950s, *Serratia* spp. were rarely isolated from human patients. Later on *S. marcescens* became more and more frequently involved in nosocomial infections and non-pigmented *S. marcescens* strains are now a serious threat in surgical and intensive care units (Daschner, 1980; von Graevenitz, 1980; Yu, 1979).

Ecology

For a long time, the confused status of *Serratia* taxonomy prevented any precise knowledge of the habitat of *Serratia* species. After the aforementioned *Serratia* species had been defined, however, it became apparent that they occupied different habitats. Table 1 shows the distribution of the major species of the *Serratia* strains isolated from small mammals and their territories, and from water, plants, and hospitalized human patients. Table 2 shows the distribution of the major biotypes of the *S. marcescens* strains isolated from these same habitats.

Serratia in Water and Soil

Water is probably the principal habitat of *S. plymuthica*. Nomenclatures resembling *S. plymuthica* (Breunig’s Kiel bacillus, “*Bacillus miniaceus*,” “*Serratia miquelii*,” and “*S. esseyana*”) have also been isolated from water. Sea-water isolates belong to the same species as terrestrial water isolates. “*Serratia marinorubra*”

Table 1. Percent distribution among *Serratia* species of 1,543 strains isolated from different habitats.

Species	Percentage of isolates in habitat				
	Small mammals ^a (92 isolates)	Animal territories ^b (51 isolates)	Water (155 isolates)	Plants ^c (137 isolates)	Hospitalized patients (1,108 isolates)

^aIsolated at the Pellegrin Hospital (Bordeaux, France) from 1968 through 1975.

^bIn addition, 72 strains of biotype A2b were isolated from infants (mostly from feces) in the neonatology ward.

was not a true marine species, as it showed no sodium requirement (P. Baumann, personal communication). Many strains of *S. fonticola* have been isolated from well waters and springs (Gavini et al., 1979). In a systematic search for *Serratia* in river water, 150 strains were isolated and were distributed in the following species: *S. marcescens* (75%), *S. liquefaciens* (11%), *S. proteamaculans* (8%), *S. grimesii* (5%), and *S. plymuthica* (1%) (F. Agbalika, F. Grimont, and P.A.D. Grimont, unpublished observations). The selective medium used (caprylate-thallosus agar) did not allow isolation of *S. fonticola*.

Strains producing the non-diffusible red pigment prodigiosin seem to be toxic to protozoa (Groscof and Brent, 1964), and this may be an ecological advantage in water and soil. However, it seems that pigmented bacteria are more often isolated from unpolluted water (from springs or wells) than from polluted water (river water downstream from cities).

In soil, *S. marcescens* might play a role in the biological cycle of metals by mineralizing organic iron and dissolving gold and copper (Parès, 1964). A mineralization role has also been attributed to cold-tolerant *Serratia* associated with low-moor peat (Janota-Bassalik, 1963).

Serratia on Plants

Serratia proteamaculans was once isolated from a leaf spot disease of the tropical plant *Protea cynaroides* (the King Protea) (Paine and Stansfield, 1919). However, the experimental lesions caused by *S. proteamaculans* on detached leaves of *Protea* suggest a hypersensitivity reaction (Paine and Berridge, 1921). Similar lesions were obtained with other species of *Serratia* (Grimont et al., 1978b). Inoculation of *S. marcescens* ICPB 2875 and *S. marinorubra* ICPB 2881 on tobacco and bean leaves also produced a typical hypersensitivity reaction (Lakso and Starr, 1970). A root disease complex of alfalfa (*Medicago sativa*) involving a *Fusarium* sp., a *Pseudomonas*

sp., and a bacterium named “*Erwinia amylovora* var. *alfalfae*” was observed by Shinde and Lukezic (1974). These isolates of “*Erwinia amylovora* var. *alfalfae*” were later identified as *Serratia marcescens* biotype A4a (Grimont et al., 1981).

Characteristic *Serratia* populations were found in figs. *S. ficaria* was recovered from most figs collected in California, Tunisia, France (Grimont et al., 1979c), Sicily (Giammanco and Amato, 1982; Grimont and Deval, 1982), and Greece (P.A.D. Grimont, unpublished observations). This species could be associated with *S. marcescens* (biogroups A1, A2, or A3) or other genera. Figs of the Calimyrna variety (Smyrna variety adapted to California) deserve special mention. Calimyrna figs contain only pistillate flowers and in order to become edible, they need to be pollinated specifically by the fig wasp *Blastophaga psenes*. The fig wasp has a life cycle limited to the caprifig, an inedible fruit produced by the caprifig tree. When a young female fig wasp makes her way out of a caprifig, she covers herself with pollen and a specific fungal and microbial flora (Phaff and Miller, 1961). The fig wasp will then enter an unpollinated caprifig of a new crop, pollinate it, oviposit in a pistillate flower, and die; or it may be carried by the wind to a Calimyrna fig—a cul-de-sac in the wasp life cycle—where the fig wasp will deposit pollen and the microbial/fungal flora in its desperate attempt to oviposit. Since 1927 (Caldis, 1927; Phaff and Miller, 1961; Smith and Hansen, 1931), a red-pigmented and a nonpigmented *Serratia* have been repeatedly isolated from caprifigs, pollinated Calimyrna figs, and fig wasps. The pigmented and nonpigmented isolates were identified as *Serratia marcescens* biotype A1b and *S. ficaria*, respectively (Grimont et al., 1979c; Grimont et al., 1981). The fact that the Calimyrna fig is internally sterile until the fig wasp enters it provides an ecological niche for these *Serratia* strains. The multiplication of *Serratia* in caprifigs or Calimyrna figs is limited, and these organisms do not

cause fig spoilage. Washing of a syconium cavity can yield 10 to 300 colony-forming-units (CFU) of *S. ficaria*.

Serratia rubidaea has been repeatedly isolated from coconuts bought in France (originating mostly from Ivory Coast) and in California (Grimont et al., 1981). The three subspecies (former biotypes B1 to B3) have been associated with coconuts, and when present, *S. rubidaea* numbered 3×10^4 to 6×10^6 CFU per gram of coconut milk or flesh (Bollet et al., 1989). It is believed that coconut palms have been disseminated worldwide from an Indo-Pacific origin. It would thus be interesting to compare the bacterial flora of coconuts collected in diverse countries.

In the course of an ecological survey and using the selective caprylate-thallos agar medium, *Serratia* species were frequently found associated with plants (Grimont et al., 1981). With respects to the presence of *Serratia*, plants (other than figs and coconuts) were classified into three prevalence groups. In the first group, which is composed of vegetables, mushrooms, mosses, and decaying plant material (i.e., wet plants), about 54% of the samples carried *Serratia* in counts varying from 2,000 to over 20,000 CFU per gram of plant (highest counts in mushrooms and leaves of radish, lettuce, cauliflower, and brussels sprout). In the second group, which is composed of grasses, *Serratia* prevalence was about 24%. In the third group composed of trees and shrubs, 8% of the samples (leaves) contained *Serratia* (10 to 300 CFU per gram).

Serratia strains isolated from plants other than figs and coconuts were distributed among eight *Serratia* species, although *S. liquefaciens* and *S. proteamaculans* were predominant (Table 1). The selective medium used (caprylate-thallos agar) was unable to support the growth of *S. fonticola*. *S. entomophila* was not isolated although this species can grow on the selective medium. Pigmented *S. marcescens* biotypes were rarely isolated from plants. Nonpigmented *S. marcescens* biogroups A3 and A4 were isolated from plants, but biogroups A5/8 and TCT were not (Table 2).

Vegetables used in salads might bring *Serratia* strains to hospitals and contaminate the patient's digestive tract. *S. marcescens*, *S. liquefaciens*, and *S. rubidaea* were found in 29%, 28%, and 11% (respectively) of vegetable salads served in a hospital in Pittsburgh (Wright et al., 1976). Similar results were found in a Paris hospital (Loiseau-Marolleau and Laforest, 1976). However, it still needs to be proven that biotypes/serotypes found in patients are the same as those found in salads. In the first described case of *S. ficaria* infection, the patient was very fond of figs (Gill et al., 1981).

Serratia in Insects

There is an extensive literature on *Serratia* associated with insects. This topic has been reviewed in detail (Bucher, 1963a; Grimont and Grimont, 1978a; Steinhaus, 1959). The insects involved belong to numerous species and genera of the orders Orthoptera (crickets and grasshoppers), Isoptera (termites), Coleoptera (beetles and weevils), Lepidoptera (moths), Hymenoptera (bees and wasps), and Diptera (flies). Taxonomic uncertainties make a retrospective evaluation of the role of *Serratia* spp. in insect infections difficult. Red-pigmented *Serratia* were easily recognized (although not determined as to species with any certainty), whereas nonpigmented strains were often referred to genera other than *Serratia*. For example, *S. proteamaculans* or *S. liquefaciens* strains were named "*Bacillus noctu- arum*" (White, 1923b), "*Bacillus melolonthae li- quefaciens*" (Paillot, 1916), "*Paracolobactrum rhyncoli*" (Pesson et al., 1955), and "*Cloaca*" B type 71-12A (Bucher and Stephens, 1959); non-pigmented *S. marcescens* strains were named "*Bacillus sphingidis*" (White, 1923a) and "*Bacil- lus apisepticus*" (Burnside, 1928).

The distribution among the various *Serratia* species of 48 collection strains isolated from insects (Grimont et al., 1979b) showed a pre- dominance of *S. marcescens* and *S. liquefaciens*. The absence of *S. plymuthica* (a pigmented spe- cies) in this collection is unexplained. Steinhaus (1941) reported the presence of *S. plymuthica* in the gut of healthy crickets (*Neombius fasciatus*), but the taxonomic schemes in vogue at that time did not allow a definite identification of *S. plymuthica*. The rarity of *S. rubidaea* (also a pig- mented species) in insects might be explained by its inability to produce chitinase—a virulence factor for insect-associated *Serratia* species (Lysenko, 1976).

The red-pigmented *Serratia* isolates associated with the fig wasp *Blastophaga psenes* and for- merly identified as *S. plymuthica* (Phaff and Miller, 1961) were reidentified as *S. marcescens* biotype A1b (Grimont et al., 1981). It is notewor- thy that *S. ficaria* was isolated from both the fig wasp *Blastophaga psenes* and from a black ant, i.e., Hymenoptera (Grimont et al., 1979c).

S. liquefaciens and *S. marcescens* were found in sugar-beet root-maggot development stages (*Tetanops myopaeformis*), suggesting an insect- microbe symbiosis, as well as a nutritional inter- dependence (Iverson et al. 1984). A relationship appeared to exist between adult fly emergence and enzymatic chitin degradation of the pupar- ium by the bacterial symbionts.

S. marcescens biotype A4b was repeatedly iso- lated from diseased honeybee (*Apis mellifera*) larvae in Sudan (El Sanoussi et al., 1987).

Serratia marcescens, *S. proteamaculans* and *S. liquefaciens* are considered potential insect pathogens (Bucher, 1960). They cause a lethal septicemia after penetration into the hemocoel. More than 70 species of insects were found to be susceptible to inoculation with *Serratia* (Bucher, 1963a). The lethal dose (LD₅₀) of inoculated *Serratia* (by intrahemocoelic injection) was calculated for several insects 10–50 *Serratia* cells per grasshopper (Bucher, 1959), 5.1 cells per adult bollweevil (Slatten and Larson, 1967), 7.5 and 14.5 cells per third and fourth instar larva (respectively) of *Lymantria dispar* (Podgwaite and Cosenza, 1976), and 40 cells per *Galleria mellonella* larva (Stephens, 1959). The LD₅₀ of ingested *S. marcescens* is much higher. The hemolymph of insects—normally bactericidal for nonpathogens—cannot prevent multiplication of potential pathogens (Stephens, 1963). Lecithinase, proteinase, and chitinase play a role in the virulence of *Serratia* for insects, and purified *Serratia* proteinase or chitinase is very toxic when injected into the hemocoel (Kaska, 1976; Lysenko, 1976). *Serratia* strains in the insect digestive tract probably originate from plants. The multiplication of *Serratia* strains in the insect digestive tract has not been quantitatively studied. Antibacterial substances in ingested leaves might interfere with bacterial multiplication, but *Serratia* strains were found resistant to these (Kushner and Harvey, 1962). How potential pathogens such as *Serratia* can enter the hemolymph from the gut is generally unknown. However, spontaneous gut rupture, which happens in about 10% of grasshoppers, may allow *Serratia* strains to invade the hemocoel (Bucher, 1959). Direct injection occurs when *Itoplectis conquisitor* contaminated with *Serratia* stings host pupae to oviposit into their bodies (Bucher, 1963b). *Serratia* epizootics are common among reared insects (Bucher, 1963a). However, until recently, no genuine epizootic of *Serratia* infection among insects had been observed in the field.

Strains of *S. entomophila* and *S. proteamaculans* can be pathogenic for the grass grub *Costelytra zealandica*, which is a major pasture pest in New Zealand (Stucki and Jackson, 1984; Trought et al., 1982). Larvae of *Costelytra zealandica* feed on grass, clover, and other plant roots. Typically, their populations grow to a peak (about 600 larvae/m²) in 4 to 6 years after the pasture is sown and then collapse (to about 50 larvae/m²). Grass grub population collapse was found associated with the presence of a disease called amber disease (Trought et al., 1982). *S. entomophila* and *S. proteamaculans* were isolated from naturally infected larvae and shown experimentally to produce the disease when transmitted orally to healthy larvae (Grimont et al., 1988; Stucki and Jackson, 1984). The bacteria are ingested from

the soil. Infected larvae stop feeding within a few days, become translucent and then amber colored and lose weight until death occurs 4 to 6 weeks later. The bacteria colonize the gut and cause disease symptoms without invading the hemocoel. Field trials have shown that control of the grass grub was feasible by application of *S. entomophila* suspensions on pastures (Jackson and Pearson 1986). Reductions of 30 to 59% in the larval populations were obtained, with 47% of the remaining larvae being infected. Such bacterial treatment resulted in a 30% increase in grass production (dry matter).

Serratia in Vertebrates

Serratia has been associated with chronic infections of cold-blooded vertebrates: nodular infection of *Anolis equestris*, the Cuban lizard (Duran-Reynals and Clausen, 1937); subcutaneous abscess of iguanid lizards (Boam et al., 1970); arthritis in the lizard *Tupinambis tequixin* (Ackerman et al., 1971); and ulcerative disease in the painted turtle *Chrysemys picta* (Jackson and Fulton, 1976). *Serratia* strains have also been recovered from the healthy, small, green pet turtle *Pseudemys scripta elegans* (McCoy and Seidler, 1973) and from geckos and turtles in Vietnam (Capponi et al., 1956).

Poultry may be contaminated with *Serratia*. A deadly *Serratia* epizootic among chick embryos was observed in a Japanese hatchery (Izawa et al., 1971). The hens carried *S. marcescens* in their digestive tract, but were themselves unaffected. Contamination of chicken carcasses with *S. liquefaciens* (Lahellec et al., 1975) and spoilage of eggs by red-pigmented *Serratia* (Alford et al., 1950) have been reported. A disseminated suppurative infection in a blue and gold macaw (*Ara ararauna*) affected with a chronic lymphoid atrophy has also been recorded (Quesenberry and Short, 1983).

Serratia strains (mostly red-pigmented) are responsible for 0.2–1.5% of cases of mastitis in cows (Barnum et al., 1958; Roussel et al., 1969; Wilson, 1963). Raw milk, therefore, may occasionally contain *Serratia* spp., and *S. liquefaciens* and *S. grimesii* are common in dairy products (Grimes and Hennerty, 1931). *Serratia* strains have been involved in septicemia in foals (Deom and Mortelmans, 1953), goats (Wijewanta and Fernando, 1970), and pigs (Brisou and Cadeillan, 1959); they have also been implicated in conjunctivitis of the horse (Carter, 1973) and abortion in cows (Smith and Reynolds, 1970). The isolation of *Serratia* from the anal sac of the red fox *Vulpes vulpes* (Gosden and Ware, 1976) has been reported.

Serratia strains have rarely been systematically searched for in the gut of animals. *S. fonticola*

was isolated in fecal samples from seven sparrows and unidentified birds. The study involved 90 wild European birds (Müller et al., 1986).

About 40% of trapped wild rodents and shrews carried *Serratia* strains in their gut without any visible sign of infection upon autopsy. The following animal species were found to carry *Serratia* spp.: 75/180, *Apodemus sylvaticus*; 7/23, *Microtus arvalis*; 3/11, *Clethrionomys glareolus*; 1/2, *Micromys minutus*; (rodents); 7/9, *Sorex*; and 1/3, *Crociodura* (shrews) (P. Giraud, F. Grimont, P.A.D. Grimont, unpublished observations). The *S. liquefaciens* complex (*S. liquefaciens*, *S. proteamaculans* and *S. grimesii*) represented 73 to 94% of all *Serratia* isolated from the gut of small mammals and from the soil and plants around traps (Table 1).

Serratia in Humans

The healthy human being does not often become infected by *Serratia*, whereas the hospitalized patient is frequently colonized or infected. At present, *S. marcescens* is the only known nosocomial species of *Serratia* (Table 1). *S. liquefaciens* and *S. rubidaea* are occasionally isolated from clinical specimens, but their pathogenic role is not established. The isolation of other *Serratia* species is anecdotal (Farmer et al., 1985; Gill et al., 1981).

Clinically, *Serratia* infections do not differ from infections by other opportunistic pathogens (von Graevenitz, 1977): respiratory tract infection and colonization of intubated patients (e.g., Cabrera, 1969; von Graevenitz, 1980); urinary tract infection and colonization of patients with indwelling catheters (e.g., Maki et al., 1973); surgical wound infection or superinfection (e.g., Cabrera, 1969); and septicemia in patients with intravenous catheterization or complicating a local infection (osteomyelitis, ocular or skin infections) (e.g., Altemeier et al., 1969). Meningitis, brain abscesses, and intraabdominal infections are more exceptional.

The relationship between a *Serratia* strain and a patient may be in the form of an ephemeral association (in gut or throat, on hands or skin), a long-term colonization (in gut or urinary tract or on the skin), or a localized or generalized infection. The form of relationship might depend on the species or strain of *Serratia*, the entry route (ingestion, injection, catheter), an ecologic advantage (antibiotic treatment), or the patient's physiologic status. Patient factors have been reviewed by von Graevenitz (1977). The localization of a hospital-acquired infection is often determined by the kind of instrumentation or intervention done (i.e., the entry route). The same strain may cause a urinary infection in a urology ward, a bronchial colonization in an

intensive care unit, and a wound infection in a surgery unit. Five epidemiological situation models can be described (adapted from Farmer et al., 1976):

Model 1: "Endogenous," nonepidemic infections. Sporadic cases of infection are observed that are associated with different *Serratia* strains. The strains are often susceptible to several antibiotics. The presence of a *Serratia* strain in feces is not a sufficient proof of the endogenous origin of the infection (*Serratia* are probably ingested daily with food). There is no prevention mechanism in this epidemiological model.

Model 2: Common source epidemics. A single strain (species, biotype, serotype) is found to colonize or infect several patients. Any type of *Serratia* can be involved, including pigmented biotypes of *S. marcescens* or environmental species (e.g., *S. liquefaciens*, *S. grimesii*, *S. rubidaea*). The strain is often susceptible to several antibiotics. An investigation can reveal a common infection source such as a breathing machine (the nebulizer and tubings should be sampled), a batch of perfusion or irrigation fluid, or an antiseptic solution. Identification of the source usually allows efficient control of the epidemic.

Model 3: Patient-to-patient spread. The *Serratia* strain involved is typically a multiresistant member of a nonpigmented biogroup of *S. marcescens* (biogroups A3, A4, A5/8, or TCT). No common source is found although several secondary sources are possible (sink or sponge in patients' rooms, high rate of fecal carriage). Disinfection of inanimate sources often has no effect on the endemic state. In fact, the reservoir is usually the infected patient, and spread among patients occurs by transient carriage on the hands of nursing or medical staff. Handling of urinary catheters, wound drains, or tracheal tubes of infected (or colonized) patients contaminates the hands of personnel (Maki et al., 1973; Traub, 1972b). Hasty hand washing in an overbusy ward or in the course of an emergency (for example, in an intensive care unit) allows the transmission of the strain to uninfected patients. These patients are often immunocompromised, treated preventively with broad spectrum antibiotics and subjected to diverse instrumentation. The situation is typically endemic with epidemic peaks in periods of time when the ward is crowded. Transfer of infected or colonized patients from one ward to another or from one hospital to another often results in the spread of the outbreak to other wards or hospitals. Prevention of this epidemiological model is difficult (and in some countries, hopeless). Proper handwashing should be enforced. Some proposed solutions deal with ward/hospital management (e.g., smaller wards, higher nurse/patient ratio, separation of infected from

noninfected patients, and separation of their respective nurses).

Model 4: Colonization of the newborn intestinal tract. Typically, an investigation of a case of *Serratia* infection leads to the discovery that most newborns are colonized by a red-pigmented, drug-susceptible strain of *S. marcescens*. A common source can be identified ("sterile" water or oily antiseptic solution used to clean the baby's skin). Contamination may occur on the first day of life. Multiplication of the strain in soiled diapers may show a red discoloration (red-diaper syndrome). Control of this situation is sometimes difficult due to the size of the reservoir. Newly sterilized solutions are quickly contaminated again. Enforcement of handwashing and frequent sterilization (daily or more) of incriminated solutions may be helpful.

Model 5: Pseudoepidemics. A drug-sensitive strain of any *Serratia* species (e.g., *S. liquefaciens*) is unreproducibly isolated from several patients who show no sign of infection. Investigation of the plastic material used to "sterilely" collect blood occasionally allows the isolation of the environmental strain that contaminated the system (plastic tubing, EDTA, or citrate solution).

The above situations are sometimes mixed or less clear. References to reports fitting with the above models can be found in Farmer et al., 1976; Schaberg et al., 1976; von Graevenitz, 1977, 1980; and Daschner, 1980.

Properties Relevant to Pathogenicity in Humans

Serratia marcescens is generally an opportunistic pathogen causing infections in immunocompromised patients. Among the possible pathogenicity factors found in *Serratia* strains are the formation of fimbriae, the production of potent siderophores, the presence of cell wall antigens, the ability to resist to the bactericidal action of serum, and the production of proteases.

In practice, each strain of the genus *Serratia* produces one to three different kinds of fimbrial hemagglutinin (HA) (Old et al., 1983). Five types of fimbriae have been observed in *serratiae*:

Type 1 fimbriae: thick, channelled fimbriae of external diameter 8 nm, associated with a mannose-sensitive hemagglutinin (MS-HA) reacting strongly with untanned fowl or guinea pig erythrocytes. The production of MS-HA is increased by serial, static broth cultures in air at either 20, 30, or 37°C. Production of MS-HA was found to be correlated with the ability of *S. marcescens* cells to attach to human buccal epithelial cells (Ismail and Som, 1982) or to the human urinary bladder surface (Yamamoto et al., 1985). This

type of HA was found to be produced by all (Old et al., 1983) or almost all (Franczek et al., 1986) *S. marcescens* strains, whether environmental or clinical, and in some strains of other *Serratia* species, except *S. plymuthica* and *S. fonticola*.

Type 3 fimbriae: thin, non-channelled fimbriae of external diameter 4–5 nm associated with a mannose-resistant hemagglutinin reacting with tannic acid-treated, but not fresh, oxen erythrocytes (MR/K-HA) (Old et al., 1983). MR/K-HA was found to be produced by almost all strains of all *Serratia* species studied by Old et al. 1983. However, Franczek et al. 1986 found MR/K-HA was more frequently produced by clinical than by environmental strains of *S. marcescens*. The MR/K-HA of all *Serratia* species, except *S. rubidaea*, were immunologically related. MR/K-HA from *S. rubidaea* was immunologically related to a *Klebsiella* MR/K-HA (Old et al., 1983).

Thin fimbriae associated with a mannose-resistant hemagglutinin reacting with fowl, guinea pig, and horse erythrocytes (type FGH MR/P-HA). This HA was produced by strains from all species except *S. plymuthica*, *S. odorifera*, and *S. fonticola* (Old et al., 1983). The corresponding fimbriae are immunologically related in the different species.

Thin fimbriae associated with a mannose-resistant hemagglutinin reacting with fowl erythrocytes only (type F MR/P-HA). This HA was produced by some *S. rubidaea* strains and was immunologically unrelated to other hemagglutinins (Old et al., 1983).

Thick, channelled fimbriae of external diameter 9–10 nm: associated with a mannose-resistant hemagglutinin reacting with fowl erythrocytes only (type F MR/P-HA). This HA was produced by some *S. fonticola* strains (Old et al., 1983).

Nearly all clinical or environmental *S. marcescens* strains produce potent siderophore(s) capable of scavenging iron from ethylenediamine di-O-hydroxyphenylacetic acid, a chelator with an association constant for ferric iron of $10^{33.9}$ (Franczek et al., 1986). *Serratia* strains (*S. marcescens* and *S. liquefaciens* were tested) generally produce enterobactin (Reissbrodt and Rabsch, 1988) but only rarely produce aerobactin (Martinez et al., 1987). A novel iron (III) transport system named SFU, was evidenced in a *S. marcescens* strain. In this system, no siderophore production is involved (Zimmermann et al., 1989).

At least two patterns of hemolysis were found to be produced by *S. marcescens* on horse blood: a clear-cut narrow zone of hemolysis under the colony, evoking the action of a cell-bound hemolysin, and a fuzzier, diffusing zone of hemolysis evoking the production of a soluble hemolysin (Grimont and Grimont, 1978b). The

latter hemolysis pattern was produced only by *S. marcescens* biogroup A4.

The cell-bound hemolysin has been studied and direct contact between erythrocytes and *S. marcescens* cells has been demonstrated (Braun et al., 1985). The lysis of erythrocytes requires actively metabolizing bacteria and does not need calcium ions. A 7.3-kilobase-pair chromosomal fragment encoding the hemolytic activity has been cloned in *Escherichia coli* and sequenced (Poole et al., 1988). Two open reading frames designated *shlA* and *shlB* have been observed. The hemolysin protein (molecular weight 165,056) is encoded by *shlA*, and the product of *shlB* somehow activates *shlA*. Protein *shlA* integrates into the erythrocyte membrane and causes osmotic lysis through channel formation (Schiebel and Braun, 1989). When an *E. coli* strain carrying the *Serratia* hemolysin gene was compared to the isogenic strain without such a gene in an experimental rat model (10^7 CFU/ml injected via urethra into the bladder), the strain carrying the hemolysin gene colonized the urinary tract more and led to a stronger inflammatory response compared to the hemolysin-negative strain (Marre et al., 1989).

A capsulated *Serratia* strain injected in the peritoneal cavity of the mouse multiplied and killed the mouse whereas an uncapsulated variant was avirulent (Ohshima et al., 1984).

Traub (1983) has shown that antibodies directed against O antigens of challenge strains afford passive protection in mice. The predominance of the O6 and O14 serotypes of *S. marcescens* in infections, the surface localization of LPS and its masking of other antigens suggests that LPS is a prime candidate for exploitation as a protective antigen in a vaccine against *S. marcescens* (Jessop, 1985).

Traub and Fukushima (1979a) classified *S. marcescens* strains into three categories with respect to their serum susceptibility. In solutions with 80% (vol/vol) of fresh serum, 88% of strains were found to be "delayed serum-sensitive" i.e., they were killed after a few hours exposure; 6% of strains were "promptly serum-sensitive" i.e., they were killed within a matter of minutes; and 6% of strains resisted an overnight exposure to serum. The delayed serum-sensitive strains were shown to be killed via the activation of the alternative pathway of the human complement system since killing was unaffected by inhibition of the classical pathway (Traub and Kleber, 1976). Conversely, promptly serum-sensitive strains were killed in a delayed fashion when the classical pathway was inhibited (Traub and Kleber, 1976). Depletion of fresh human serum of C3 with hydrazine hydrate completely abolished the bacterial activity against both promptly serum-sensitive and delayed serum-sensitive strains

(Traub and Fukushima, 1979a). Complement is of prime importance with respect to efficient opsonization and subsequent phagocytic killing by human peripheral blood granulocytes (Traub, 1982). In an intraperitoneal mouse model, treatment of animals with cyclophosphamide (generating a leukopenia) or zymosan (depletion of complement) did not increase susceptibility to *S. marcescens*. A combination of both treatments was necessary to significantly raise susceptibility to *S. marcescens* (Traub et al., 1983).

Crude culture filtrates have been shown to produce dermal hemorrhage after intradermal inoculation (Liu, 1961), corneal damage (Kreger and Griffin, 1975), and endophthalmitis after intravitreal injection (Salceda et al., 1973). These are due to one or more extracellular proteases produced by *S. marcescens*. Up to four proteases were purified (Lyerly and Kreger, 1979; Matsumoto et al., 1984)—two metalloproteases of 56 and 60 kDa and two thiol proteases of 73 kDa. These proteases play a prominent role in the pathogenesis of experimental pneumonia (Lyerly and Kreger, 1983) and keratitis (Lyerly et al., 1981). Most studies focused on the 56-kDa protease. Protease(s) were shown to cause: 1) liquefactive necrosis of the cornea (Kamata et al., 1985); 2) inactivation of five major proteinase inhibitors including α_1 -proteinase inhibitor (Virca et al., 1982), α_2 -macroglobulin, C1 inhibitor, α_2 -antiplasmin, and antithrombin III (Molla et al., 1989), which participate in regulating various cascade mechanisms (fibrinolysis and clotting cascade, complement system, inflammatory response); 3) degradation of immunoglobulins G and A, fibronectin, and other serum proteins (Molla et al., 1986; Traub and Bauer, 1985); 4) a potent toxic effect of fibroblasts that was mediated by internalization of a proteinase- α_2 -macroglobulin complex via the α_2 -macroglobulin receptor, followed by regeneration of the proteinase activity in the cell (Maeda et al., 1987); 5) activation of the Hageman factor-kallikrein system generating kinin, which leads to enhanced vascular permeability (Matsumoto et al., 1984); and 6) cleavage of human C3 and C5 to yield leukotactic fragments (Ward et al., 1973).

Although resistance plasmids probably play no role in the virulence of *S. marcescens* in experimental models (Traub et al., 1983), multiple drug resistance may affect the course and prognosis of infections.

Non-pigmented strains of *S. marcescens* are generally more resistant to antibiotics than pigmented strains because they often harbor resistance plasmids. Environmental strains of *S. marcescens* or strains isolated before the antibiotic era are resistant to colistin, cephalothin, ampicillin (low level of resistance), tetracycline,

and nitrofurantoin and are usually susceptible to carbenicillin, third-generation cephalosporins, chloramphenicol, streptomycin, kanamycin, gentamicin, tobramycin, amikacin, trimethoprim/sulfamethoxazole, fosfomycin, nalidixic acid, and other quinolones (P.A.D. Grimont, unpublished observations). Clinical strains harboring plasmids often show additional resistance to various antibiotics (Farrar, 1980; Hedges, 1980), with a single plasmid being able to confer resistance to one to eleven antibiotics (Hedges, 1980; Olexy et al., 1982). Mutants resistant to nalidixic acid are often encountered in urology wards, and these mutants are often resistant to other quinolones. The antibiotics most often active against nosocomial strains of *S. marcescens* are amikacin, moxalactam, and cefotaxime. However, some strains may produce enzymes inactivating amikacin (Farrar, 1980) or may overproduce a class C β -lactamase (low-level resistance to cefotaxime and some other third-generation cephalosporins), which may combine with decreased permeability to β -lactams (high resistance to cefotaxime and some other third-generation cephalosporins) (Hechler et al., 1989).

Compounds Produced by *Serratia*

Pigments

Prodigiosin, a nondiffusible red pigment, is a secondary metabolite formed by the enzymatic condensation of 2-methyl-3-amylpyrrole (MAP) and 4-methoxy-2,2'-bipyrrole-5-carboxyaldehyde (MBC), leading to a tripyrrole derivative, 2-methyl-3-amyl-6-methoxyprodigiosene (Williams and Qadri, 1980). Little is known about the biosynthetic pathways of MAP or MBC, except that a proline molecule is incorporated intact into one of the pyrrole groups of MBC (Williams and Qadri, 1980). Pigment synthesis requires air, probably molecular oxygen. In the genus *Serratia*, prodigiosin is only produced by strains of *S. marcescens*, *S. plymuthica*, and *S. rubidaea*. In *S. marcescens*, prodigiosin is produced by biogroups A1 and A2/6 and never by biogroups A3, A4, A5/8, or TCT (Grimont, P. A. D., 1977). Nonpigmented strains of biogroups A1 or A2/6 are often blocked in the synthesis of either MAP or MBC (Grimont, P. A. D., 1977; Williams and Qadri, 1980). Strains in the nonpigmented biogroups are likely to lack the condensing enzyme (Ding and Williams, 1983). Some genes encoding prodigiosin biosynthesis were cloned by Dauenhauer et al. 1984 and expressed in *Escherichia coli*. The clones obtained had acquired the ability to condense MAP with MBC or to produce MAP in addition to the condensing enzyme.

Strains belonging to the ubiquitous biotype A4 can synthesize a pink diffusible pigment called

pyrimine (Grimont and Grimont, 1984; Williams and Qadri, 1980). Pyrimine, or ferrosamine A, is a ferrous complex of L-2(2-pyridyl)-D'-pyrroline-5-carboxylic acid, a secondary metabolite also known to be produced by *Erwinia rhapsodica* (Feistner et al., 1983).

A yellow diffusible pigment, 2-hydroxy-5-carboxymethylmuconic acid semialdehyde, is produced from the *meta* cleavage of 3,4-dihydroxyphenylacetic acid (3,4-DHP) by the enzyme 3,4-DHP 2,3-dioxygenase (Trias et al., 1988). This enzyme is induced by tyrosine in all *S. marcescens* strains. However, presently only *S. marcescens* strains of biotype A8a, which have lost the ability to grow on aromatic compounds, can produce the yellow pigment. An uncolored muconic acid, β -*cis-cis*-carboxymuconic acid, can be produced by the *ortho* cleavage of 3,4-dihydroxybenzoate.

Biosurfactants

Both pigmented and some nonpigmented strains of *Serratia marcescens* produce a biosurfactant that can act as a wetting agent. This wetting agent is produced in large amounts at 30°C but not at 37°C during the stationary phase of growth. Three aminolipids, designated W1 to W3 and having the wetting activity, were separated by thin-layer chromatography (Matsuyama et al., 1986). W1 was identified as serratamolide, a cyclodepsipeptide earlier discovered by Wasserman et al. 1961.

Fatty Acids

The major fatty acid components in whole-cell methanolysates of *Serratia* species are 3-hydroxy-tetradecanoic, *n*-hexadecanoic, hexadecanoic, and octadecanoic (not separated from octadecadienoic) acids. These contribute 50–80% of the component fatty acids in each strain. Significant quantities are also contributed by *n*-tetradecanoic acid (Bergan et al., 1983).

Flavors

Alkyl-methoxypyrazines are responsible for the potato-like odor produced by all strains of *S. odorifera* and *S. ficaria* and some strains of *S. rubidaea*. The major alkyl-methoxypyrazine produced by these *Serratia* strains is 3-isopropyl-2-methoxy-5-methylpyrazine. Minor compounds include 3-*sec*-butyl-2-methoxy-5(6)-methylpyrazine and 3-isobutyl-2-methoxy-6-methylpyrazine (Gallois and Grimont, 1985). Production of these three molecules by other bacterial species has never been observed. The food industry uses pyrazines to improve the flavor of some products.

Enzymes

The most probable potential use of chitinase is in the treatment of the chitin-containing wastes produced by the seafood packing industry, bio-control agents against plant pathogenic fungi, production of adhesives and wound dressings, heavy metal recovery from waters, delayed-release agrochemicals or drugs, and dialysis membranes (Joshi et al., 1989). *S. marcescens* produces five proteins (molecular masses of 57, 52, 48, 36, and 21 kDa) with chitinolytic activity (Fuchs et al., 1986) whereas *S. liquefaciens* produces three proteins (molecular masses of 56, 51, and 36 kDa) with such activity (Joshi et al., 1989). The sequences of two *S. marcescens* chitinase genes, *chiA* encoding the 57 kD enzyme and *chiB* encoding the 52 kD enzyme, have been published (Jones et al., 1986; Harpster and Dunsmuir, 1989).

Biotechnology

Serratia strains have been used in whole-cell bioconversion processes. Resting-cell suspensions of *S. marcescens* are able to convert vanillin to vanillic acid. At high substrate concentration (0.3%), 75% vanillin is converted (Perestello et al., 1989). 2,5-Diketogluconic acid, a key intermediate in the synthesis of ascorbic acid, can be produced from glucose at 20°C by *S. marcescens* (without requirement for a cofactor) and by *S. liquefaciens* and *S. grimesii* when supplied with the cofactor, pyrroloquinoline quinone (Bouvet et al., 1989).

Some genetic tools are available to construct *S. marcescens* strains of biotechnological interest. These tools include general transduction (Matsumoto et al., 1973), transformation (Reid et al., 1982), and use of nuclease-deficient, antibiotic-sensitive, and restrictionless mutants (reference is not an exact match Takagi and Kisumi, 1985). Recombinant strains obtained were histidaseless regulatory mutants producing L-histidine (Kisumi et al., 1977), L-arginine-producing mutants (Kisumi et al., 1978), an isoleucine-producing strain (Komatsubara et al., 1980), and a threonine-hyperproducing strain (Komatsubara et al., 1983).

Isolation

Underlying Principles

Pigmented species and biotypes of *Serratia* often exhibit pink or red colonies on nutrient agar. Use of low-phosphate agar without glucose, such as peptone-glycerol agar (Difco peptone,

5 g; glycerol, 10 ml; Difco agar, 20 g; distilled water, 1 liter), is best in order to demonstrate pigmentation (Williams and Hearn, 1967). Although the genus *Serratia* includes all the red-pigmented enterobacteria, identification of a pink or red colony should be confirmed by biochemical tests because a few nonenterobacteria may also produce prodigiosin (see "Introduction"). On nutrient agar, nonpigmented species or biotypes of *Serratia* give opaque-whitish, mucoid, or transparent smooth colonies. None of these traits is specific for the isolation of *Serratia* from a mixture of enteric bacteria. Colonies of *S. odorifera* and *S. ficaria* and occasionally *S. rubidaea* give off a specific, potato-like odor. Detection of this odor may suggest the presence of at least one colony of that species on the plate.

The salt tolerance and relatively low minimal growth temperature of all *Serratia* species may help devise a means of enriching them. A nutrient broth containing 4% NaCl, incubated at 15–20°C, will allow multiplication of *Serratia* but not of *Enterobacter cloacae* or *Aeromonas hydrophila* (P. A. D. Grimont, unpublished observations). This procedure has been used by us, but no systematic study of its effectiveness has been conducted.

Strains of the genus *Serratia* do not normally require addition of growth factors to a minimal medium. Thus, an enrichment medium for *Serratia* can be a minimal medium with a carbon source that is commonly used by *Serratia* spp. but not by non-*Serratia* spp.

Production of extracellular gelatinase, lecithinase, and DNase are essential characteristics of the genus *Serratia* (Ewing, 1986; Grimont et al., 1977b), *S. fonticola* excepted. Agar media that show the presence of one or a combination of extracellular enzymes can be used to differentiate *Serratia* colonies.

Finally, *Serratia* spp. are resistant to several compounds, including colistimethate, cephalothin (Greenup and Blazevic, 1971), and thallium salts (Starr et al., 1976), and one of these compounds can be used to make enrichment or differential media selective for *Serratia*. However, some *S. plymuthica* or *S. rubidaea* strains may be more susceptible to colistimethate, cephalothin, or ampicillin than is *S. marcescens*.

No medium has yet been devised to selectively isolate one particular *Serratia* species (other than *S. marcescens*), although specific carbon sources or conditions are listed in taxonomic papers (Grimont et al., 1977b). Occasionally, a selective medium may be devised according to a specific pattern of antibiotic resistance displayed by a nosocomial strain of *S. marcescens* (Denis and Blanchard, 1975), but such media cannot be of general utility.

Selective Media Based on DNase Production and Antibiotic Resistance

Farmer et al. 1973 proposed the following deoxyribonuclease-toluidine blue-cephalothin (DTC) agar.

DTC Agar for Isolating *Serratia* (Farmer et al., 1973)

Deoxyribonuclease test agar (BBL)	21 g
Agar (Difco)	2.5 g
Toluidine blue O	0.05 g
Distilled water	500 ml

Mix on a mechanical stirrer until the dye dissolves, autoclave with a Teflon stirring bar at 121°C for 15 min, cool to 50°C, add 5 ml (500 mg) of cephalothin (Keflin injectible, Eli Lilly), stir and dispense in sterile petri dishes.

Typically, *Serratia* spp. grow on this blue DTC medium producing a red halo extending several millimeters around the colonies. "False negatives" (no growth or no halo) are very rare among *S. marcescens* isolates, but several strains of *S. rubidaea* and *S. plymuthica* failed to give the proper reaction (Starr et al., 1976).

A medium with DNase test agar, toluidine blue, cephalothin (30 µg/ml and colistimethate (30µ/ml) has been proposed by Cate (1972); and a medium with DNase test agar, toluidine blue, egg yolk, and cephalothin (100µ/ml) has been proposed by Goldin et al. 1969. The latter combines DNase and lecithinase detection.

Berkowitz and Lee (1973) devised the following medium for the isolation of *S. marcescens*:

DNase Medium for Isolating *Serratia marcescens* (Berkowitz and Lee, 1973)

Deoxyribonuclease test agar with methyl green (Difco)	42 g
L-Arabinose	10 g
Phenol red	0.05 g
Methyl green, 1%	4 ml
Distilled water	up to 1 liter

After autoclaving, add ampicillin (5 µg/ml), colistimethate (5 µg/ml), cephalothin (10 µg/ml), and amphotericin B (2.5 µg/ml).

Serratia colonies hydrolyze DNA, and the green component of the medium's dark color disappears around the colonies. *S. marcescens* (or *S. entomophila*), unable to ferment L-arabinose, will give colonies surrounded by a red halo, whereas other *Serratia* species will give a yellow halo. The other *Serratia* species, however, may be inhibited by the antibiotic mixture. Wright et al. 1976 used this medium to isolate and enumerate *S. marcescens* from vegetable salads.

Selective Media Based on Carbon-Source Utilization

A minimal medium with *meso*-erythritol as the sole carbon source was devised by Slotnick and Dougherty (1972). A modification of this

medium that included the antiseptic "Irgasan" (4',2',4'-trichloro-2-hydroxydiphenylether), has been proposed (Lynch and Kenealy, 1976). Unfortunately, *Serratia liquefaciens*, *S. plymuthica*, *S. entomophila*, *S. proteamaculans* biotypes Clc and RB, *S. odorifera* biotype 1, and the nosocomial biotypes A5, A8a, A8b, A8c and TCT of *S. marcescens* cannot grow with erythritol as sole carbon source (Grimont et al., 1977b; Grimont et al., 1978a; Starr et al., 1976). Therefore, these media should not be used in epidemiological or ecological surveys unless the study is knowingly limited to erythritol-positive *serratiae*.

A minimal medium with *meso*-inositol as sole carbon source has been proposed for the selective isolation of *Klebsiella pneumoniae* and *Serratia* spp. (Legakis et al., 1976). However, only a few genera and species have been studied by these authors, and it has been shown (Grimont et al., 1977b) that *Enterobacter aerogenes*, *E. cloacae*, *Erwinia herbicola*, and pectinolytic *Erwinia* spp. can also grow on a minimal medium with inositol as sole carbon source.

A caprylate-thallos (CT) agar medium has been devised for the selective isolation of all *Serratia* species and biotypes. This CT agar, derived from M70 minimal medium (Véron, 1975), is made up as follows (Starr et al., 1976):

CT Agar for Selective Isolation of *Serratia* (Starr et al., 1976)

First, a trace element solution (Véron, 1975) is prepared:

H ₃ PO ₄	1.96 g
FeSO ₄ ·7H ₂ O	0.0556 g
ZnSO ₄ ·4H ₂ O	0.0287 g
MnSO ₄ ·4H ₂ O	0.0223 g
CuSO ₄ ·5H ₂ O	0.025 g
Co(NO ₃) ₂ ·6H ₂ O	0.003 g
H ₃ BO ₃	0.0062 g
Distilled water	1 liter

Store at 4°C (keeps well for at least 1 year). Then the following solutions (solution A and solution B) are prepared:

Solution A:

CaCl ₂ ·2H ₂ O	0.0147 g
MgSO ₄ ·7H ₂ O	0.123 g
KH ₂ PO ₄	0.680 g
K ₂ HPO ₄	2.610 g
Trace element solution (see above)	10 ml
Caprylic acid	1.1 ml
Yeast extract (Difco)	
(5% wt/vol solution)	2 ml
Thallos sulfate	0.25 g
Distilled water	up to 500 ml

The pH is adjusted to 7.2 with NaOH. Autoclave at 110°C (or 120°) for 20 min.

Solution B:

NaCl	7 g
(NH ₄) ₂ SO ₄	1 g
Agar (Difco)	15 g
Distilled water	500 g

The pH is adjusted to 7.2. Autoclave at the same time as solution A. After autoclaving, solutions A and B are mixed aseptically, and the resulting medium is poured in thick layers into sterile, plastic petri dishes (25–30 ml for petri dishes 9–10 cm in diameter). The medium is no longer effective if it is remelted, but plates of CT agar keep well for several weeks at 4°C if contamination and desiccation are prevented.

CT agar is very useful for the isolation of *Serratia* spp. (except *S. fonticola*) from feces, sputum, and any other polymicrobial clinical sample. *Serratia* colonies are apparent within 3 days, and further incubation allows colonies grow (2–5 mm). Occasionally, *Providencia* spp., *Acinetobacter* spp., or *Pseudomonas* spp. may develop colonies on this medium. Other bacteria give only pinpoint colonies. When samples are from the natural environment or food, the results are less clear, especially if the sample contains nutrients. Several colonies must then be checked for DNase. Preenrichment in nutrient broth with 4% NaCl, incubated overnight at 20°C, can be used; about 0.1 ml of the enrichment culture is streaked onto CT agar. Broth that has supported overnight bacterial growth usually does not contain enough nutrients to adversely affect the selective isolation of *Serratia* spp. (P. A. D. Grimont, unpublished observations).

Identification

The usual methods for the identification of serratiae and other Enterobacteriaceae can be found in Ewing (1986). However, following the pioneering example of Stanier et al. (1966) with the pseudomonads, developments in enterobacterial taxonomy (Bouvet et al., 1985; Grimont and Ageron, 1989; Grimont et al., 1977b; Grimont et al., 1988) have demonstrated the usefulness of carbon source utilization tests. Also, it should be noted that utilization tests are preferable to fermentation tests since strains able to utilize a polyalcohol sometimes fail to produce enough acid products to give a positive reaction in fermentation tests. Although all species can be identified with carbon source utilization tests, some conventional tests can also be used: tetrathionate-reduction and β -xylosidase tests are useful in clinical identification (Le Minor et al., 1970; Brisou et al., 1972). The methodology of carbon source utilization tests and other procedures that are not in general use, but are essential to *Serratia* identification, are detailed herein.

Conditions of Incubation

Best results are obtained when *Serratia* cultures are incubated at 30°C. At 37°C, pigmentation often fails to appear, and the Voges-Proskauer

test is often negative. *S. plymuthica* may even fail to grow at 37°C. Otherwise, there is little difference between the results of tests held at 30°C and those held at 37°C as far as *S. marcescens* is concerned.

Carbon Source Utilization Tests

Two methods can be used for carbon utilization tests: a minimal agar medium or API strips (API System, La Balme-les-Grottes, France).

The minimal agar medium employs the same M70 medium (Véron, 1975) used in the caprylate-thallos selective agar (see the recipe), but omits the yeast extract, thallos sulfate, and caprylate from solution A. Neutralized carbon sources (the purest brand available) are added to solution A to give a 0.1% final concentration (weight of the anion/vol) in the complete medium (0.2% in the case of carbohydrates). Sterilization of the carbon source in aqueous solution is achieved by filtration through membrane filters or by heating at 80°C for 20 min. Plates are examined for growth after 4 days (early reading) and 14 days (late reading).

The API strip method uses API 50 CH (containing 49 carbohydrates), API 50 AO (49 organic acids), and API 50 AA (49 aminoacids) galleries and a minimal medium containing growth factors provided by the manufacturer. These were described by Gavini et al. (1980). Since about one-third of the carbon sources are useless in the study of the Enterobacteriaceae, we use special galleries containing 99 selected carbon sources (including new compounds not included in the above-mentioned galleries). The inoculated galleries are examined for growth after 2 days (early reading) and 4 days (late reading). These galleries have been used for the description of several bacterial groups (Bouvet et al., 1985; Grimont et al., 1988; Grimont and Ageron, 1989).

In our experience, carbon source utilization tests (CSUT) gave reproducible and clear-cut results. Utilization of carbohydrates and polyalcohols often give more useful results than fermentation tests (FT). More than 95% of CSUT and FT using D-xylose, L-arabinose, trehalose, sorbitol, sucrose, and rhamnose gave the same results (P. A. D. Grimont, 1977). However, results with CSUT and FT are not parallel when adonitol, inositol, cellobiose, and lactose are studied. Whereas almost all *Serratia* strains can grow on inositol, acid from inositol was produced by only 76% of *S. marcescens*, 36% of *S. rubidaea*, 92% of *S. liquefaciens*-*S. proteamaculans* and 35% of *S. plymuthica* strains within 2 days. CSUT with adonitol is a very good test for separating *S. marcescens* from *S. liquefaciens* (99% vs. 0% positive strains, respectively), but

FT with adonitol is a poor test for separating these two species (32% vs. 0% positive strains in 2 days, respectively).

Glucose Oxidation Test

The Lysenko test (Lysenko, 1961) was extensively modified by Bouvet et al. 1989. A 1-liter portion of glucose oxidation medium is composed of basal medium containing 8 g of nutrient broth (Difco), 0.02 g of bromocresol purple, and 0.62 g of $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ (2.5 mM). To 9.2 ml of autoclaved (121°C, 15 min) basal medium is added 0.4 ml of a filter-sterilized 1 M D-glucose solution (final concentration, 40 mM). This medium is supplemented with 0.4 ml of a fresh, sterile 25 mM iodoacetate solution (final concentration, 1 mM). The glucose oxidation medium is distributed (0.5 ml portions) into glass tubes (11 by 75 mm), which are plugged with sterile cotton wool. Bacteria grown overnight at 20 or 30°C on tryptocasein soy agar (Diagnostics Pasteur, Marnes-la-Coquette, France) supplemented with 0.2% (wt/vol) D-glucose are collected with a platinum loop, suspended in a sterile 2.5 mM MgSO_4 solution and adjusted to an absorbance (at 600 nm) of about 4. Glucose oxidation medium is then inoculated with 50 μl of bacteria suspension and vigorously shaken at 270 strokes per minute overnight at 20 or 30°C. The test is positive if a yellow color develop (acid production). Otherwise, the medium remains purple. When negative, the glucose oxidation test is repeated in the presence of 10 μM pyrroloquinoline quinone (PQQ). The control strains used are the type strains of *S. marcescens* (positive without requirement for PQQ) and *S. liquefaciens* (positive only when PQQ is supplied) (Bouvet et al., 1989).

Gluconate and 2-Ketogluconate Dehydrogenase Tests

The gluconate dehydrogenase test is performed as follows (Bouvet et al., 1989): Bacteria are grown overnight at 20°C on tryptocasein soy agar supplemented with 0.2% D-gluconate, then collected with a platinum loop and suspended in sterile distilled water to an absorbance (at 600 nm) of about 4. The reaction medium contains 0.2 M acetate buffer (pH5), 1% (wt/vol) Triton X-100, 2.5 mM MgSO_4 , 75 mM gluconate, and (added immediately before use) 1 mM iodoacetate. A control medium contains the same ingredients except gluconate. The reaction medium and the control medium are dispensed (100 μl portions) into 96-well microtiter plates (Dynatech AG, Denkendorf, Germany). Bacterial suspensions (10 μl) are added to the reaction and the

control media, and the microtiter plates are incubated at 20°C for 20 min. Then, 10- μl portions of a 0.1 M potassium ferricyanide solution (kept in the dark at room temperature for no longer than 1 week) are added to the wells, and the plates are gently shaken and incubated at 20°C for 40 min. Then 50 μl of a reagent containing $\text{Fe}_2(\text{SO}_4)_3$, 0.6 g; sodium dodecyl sulfate, 0.36 g; 85% phosphoric acid, 11.4 ml; distilled water to 100 ml is added to each well. The plates are examined for the development of a green- to-blue color (due to Prussian blue) within 15 min at room temperature. The color in the uninoculated control medium remains yellow. The suggested control strains used are *Escherichia coli* K-12 (negative) and the type strain of *Serratia marcescens* (positive).

The 2-ketogluconate dehydrogenase test is the same as above, except that the control and reaction media are adjusted to pH 4.0, and 2-ketogluconate is used in place of gluconate in the reaction medium. Suggested control strains used are *Escherichia coli* K-12 (negative) and the type strain of *Serratia marcescens* (positive at 20°C, not at 30°C) (Bouvet et al., 1989).

Tetrathionate Reductase Test

The tetrathionate reductase test was found to be very useful for the identification of *Serratia* spp. The liquid medium of Le Minor et al. (1970) is described below:

Tetrathionate Reductase Test for Identifying *Serratia* spp. (Le Minor et al., 1970)

$\text{K}_2\text{S}_4\text{O}_6$	5 g
Bromthymol blue (0.2% aqueous solution)	25 ml
Peptone water (peptone [Difco], 10 g; NaCl, 5 g; distilled water, 1 liter)	Up to 1 liter
Adjust pH to 7.4. Filter-sterilize and dispense 1 ml into 12-x-120-mm tubes. Within 1 or 2 days, reduction of tetrathionate will acidify the medium, indicated by a yellow color. Negative tubes remain green or turn blue.	

Voges-Proskauer Test

Results of the Voges-Proskauer test are variable with some *Serratia* spp., probably because the end products of the butanediol pathway are metabolized (Grimont et al., 1977b). Many strains of *S. plymuthica* and *S. odorifera* give negative results with O'Meara's method (O'Meara, 1931) and positive results with Richard's procedure (Richard, 1972). In Richard's procedure, 0.5-ml aliquots of Clark and Lubs medium (BBL) are inoculated in 16-mm-wide test tubes. After overnight incubation at 30°C, 0.5 ml of α -naphthol (6 g in 100 ml absolute ethyl alcohol) and 0.5 ml of 4 M NaOH are added. Positive tubes will turn red.

Gas Production

Gas production differentiates *Serratia marcescens* from *S. liquefaciens*—*S. proteamaculans* better when glucose agar is used than when a liquid medium with a Durham inverted tube is used (Grimont et al., 1977b). Glucose agar consists of nutrient agar (meat extract [Liebig], 3 g; yeast extract [Difco], 10 g; agar [BBL], 15 g; distilled water to 1 liter; pH 7.4) supplemented with 1% (wt/vol) glucose. Dispense into tubes (160 × 10 mm). Autoclave 20 min at 120°C, cool at 50°C, and inoculate before the agar sets. Tubes are examined for bubbles of gas for up to 3 days.

β-Xylosidase

The method of Brisou et al. (1972) for demonstrating β-xylosidase can conveniently be adapted for use with sterile microculture plates. Aqueous (1% wt/vol) p-nitrophenyl-β-xyloside is dispensed into the wells in 0.05-ml amounts, followed by 0.05 ml of a fresh bacterial suspension in 0.25 M phosphate buffer, pH 7. Plates are examined for a yellow color after 24 h.

Identification of *Serratia* at the Genus Level

Members of the genus *Serratia* share the characteristics defining the family *Enterobacteriaceae*. Only occasionally can a nitrate-negative strain be isolated. The properties that best define the genus *Serratia* are listed in Table 3. Although lipase activity on tributyrin or corn oil is listed, *S. odorifera* strains are only weakly lipolytic. A weak urease activity, lack of motility, or presence of a capsule are occasionally observed. *Serratiae* are clearly differentiated from *Klebsiella* spp., *Enterobacter aerogenes*, and *E. cloacae* by production of gelatinase, lipase, DNase, and by growth on caprate or caprylate as sole carbon source. Some soft-rot *Erwinia* spp. produce extracellular proteinase and DNase, but these strains are pectinolytic and lack glucose and gluconate dehydrogenases (Grimont et al., 1977b).

Identification of *Serratia* Species

The characteristics best allowing identification of each *Serratia* species are given in Tables 4 and 5. Carbon source utilization tests are invaluable for unambiguous identification. Indole production by *S. odorifera* is not reproducibly observed when peptone water is used. A defined medium containing tryptophane (e.g., “urée-indole” medium, Diagnostics Pasteur, Marnes-la-Coquette, France; or the indole test in API 20E strips) gives consistently positive results with this species. With the use of classical tests (Ewing, 1986), *S. plymuthica* may be confused either with

Without addition of pyrroloquinoline quinone. All species produce gluconate from glucose in the presence of pyrroloquinoline quinone.

^bSymbols: +, positive for 90% or more strains in 2-day reading; –, negative for 90% or more strains in 4-day reading; d, test used to differentiate biotypes; v, variable reactions; (), 4-day reading; ND, not determined.

tests can help to sort out these "atypical" strains: after examining more than 5,000 *Serratia* strains, we have found no *S. liquefaciens*, no *S. grimesii*, and no *S. plymuthica* strains that were able to grow on adonitol and erythritol and no *S. rubidaea* strains able to grow on sorbitol as sole carbon source.

Identification of *Serratia* Biogroups and Biotypes

Biotypes in *Serratia marcescens*, *S. proteamaculans*, *S. plymuthica*, and *S. rubidaea* were first defined by numerical taxonomy (Grimont et al., 1977b). We recognize 18 biotypes in *S. marce-*

scens, 4 in *S. proteamaculans*, 2 in *S. grimesii*, 3 in *S. rubidaea*, 2 in *S. odorifera*, and 2 in *S. entomophila*. Characteristics of these biotypes are given in Tables 6–9. Carbon source utilization tests are major elements in the identification of these biotypes. Multipoint inoculation devices (e.g., Denley Multipoint Inoculator, Denley Instruments, Ltd., Bolney Cross, Bolney, Sussex, England), are the most useful for biotyping 20 or more strains at a time. Biotype identification is faster (1–4 days) when API strips containing carbon sources are used. Alternatively, filter paper disks impregnated with each carbon source can be deposited on an inoculated minimal agar

(Sifuentes-Osornio and Gröschel, 1987). Differentiation between *S. proteamaculans* biotypes Cla and Clb is superfluous; electrophoresis of proteinases (Grimont et al., 1977a) could not discriminate between these two biotypes.

Serotyping of *Serratia marcescens*

The systematic inventory of somatic (O) antigens of *S. marcescens* began in 1957 (Davis and Woodward, 1957). Flagellar antigens (H) were described (Ewing et al., 1959) and an antigenic scheme was developed (Ewing, 1986; Ewing et al., 1959; Le Minor and Pigache, 1977, 1978; Le

Biotyping of *S. marcescens* is epidemiologically useful (Grimont and Grimont, 1978b; Sifuentes-Osornio et al., 1986). Pigmentation occurs only in five *S. marcescens* biotypes: A1a, A1b, A2a, A2b, and A6. The 13 other *S. marcescens* biotypes correspond to nonpigmented strains: A3a, A3b, A3c, A3d, A4a, A4b, A5, A8a, A8b, A8c, TCT, TT, and TC. Biotypes TT and TC are rarely found and their ecological-epidemiological significance is unknown. Nonpigmented biotypes A3abcd and A4ab are ubiquitous, whereas nonpigmented biotypes A5, A8abc, and TCT seem restricted to hospitalized patients (these biotypes can however be isolated from sewage-polluted river water). Pigmented biotypes are ubiquitous.

Minor and Sauvageot-Pigache, 1981; Le Minor et al., 1983; Sedlak et al., 1965; Traub, 1981, 1985; Traub and Fukushima, 1979b; Traub and Kleber, 1977). The present system consists of 24 somatic antigens (O1 to O24) and 26 flagellar antigens (H1 to H26). Serotyping of *S. marcescens* is not easy. Cross-reactions occur between O antigens 2 and 3 (the common antigen is referred to as Co/2, 3); 6 and 7; 6, 12, and 14; and 12, 13, and 14 (the common antigen is referred to as Co/12, 13, 14). Some strains seem to have more than one O-factor (e.g., O3,21). Cross-reactions between O6 and O14 are so extensive that the epidemiological distinction between these two antigens (now referred to as O6/O14) was abandoned.

The accuracy of the O-agglutination test with boiled antigens has been questioned (Gaston et al., 1988; Gaston and Pitt, 1989a). Immunoblotting with electrophoresed lipopolysaccharide (LPS) antigens showed that O-agglutinating sera often reacted with a heat-stable surface antigen rather than with LPS. This heat-stable surface antigen masks the expression of O-specific LPS antigens. Gaston and Pitt (1989b) proposed a simple dot enzyme immunoassay (dot EIA) that could offer greater accuracy than agglutination tests for serotype identification. Most strains possess distinct acidic polysaccharides of microcapsular origin. Oxley and Wilkinson (1988a) have shown that the O13 antigen is a microcapsular, acid polymer, rather than an integral part of the lipopolysaccharide. No high-molecular weight LPS corresponding to O-side chain material was detected in O-serogroup reference strain O11 or O13 (Gaston and Pitt, 1989a). The O6/O14 antigen is a partially acetylated acidic glucomannan (Brigden and Wilkinson, 1985). Three different neutral polymers (O-side chain polysaccharides) have been found in three O14 strains. Each of these polymers has been shown to occur also in strains of serogroups O6, O8, or O12. The polymer with a disaccharide repeating-unit of D-ribose and 2-acetamido-2-deoxy-D-galactose present in the O12 reference strain, the O14:H9 reference strain, and in a O13:H7 reference strain all correspond to the Co/12,13,14 antigen shared by these strains (Brigden et al., 1985; Brigden and Wilkinson, 1983; Oxley and Wilkinson, 1988b).

To overcome the tediousness of measuring flagellar agglutination, an immobilization test in semisolid agar has been described for determination of H antigens (Le Minor and Pigache, 1977). The technique is facilitated by the use of pools of nonabsorbed sera. No anti-H:9 serum is needed in pools, as bacteria with H:9 antigen are immobilized by anti-H:8 and anti-H:10 sera. Once the unknown strain is immobilized by a serum pool, corresponding individual sera are

Table 10. Correlation between biogroups and serotypes in *Serratia marcescens*.

^aBiogroup A1 is composed of biotypes A1a and A1b; A2/6 is composed of A2a, A2b, and A6; A3 of A3a, A3b, A3c, and A3d; A4 of A4a and A4b; A5/8 of A5, A8a, A8b, and A8c; and TCT of TCT and TT.

used to achieve final identification of H antigens. The following absorbed sera need to be prepared: anti-H:8 absorbed by H:10; anti-H:10 absorbed by H:8; and anti-H:3 absorbed by H:10. Other cross-reactions are overcome by dilution of sera. The immobilization test works because H antigens are monophasic in *S. marcescens*.

A total of 175 complete (O+H) serotypes have been identified at this time. No plasmid or phage has yet been found to alter the serotype of a strain.

Some striking correlations between antigenic composition and biotype have been shown (Grimont et al., 1979a). Pigmented biotypes and non-pigmented biotypes are antigenically segregated. Serotyping subdivides the biotypes, but when two biotypes correspond to the same serotype, these biotypes usually differ by only one biochemical reaction. Biotypes can be united into "biogroups" in order to clarify biotype-serotype correlation (Table 10). These biogroups may be valid infraspecific taxa.

Serotyping of Other Species

An antigenic scheme for *S. ficaria* is presently available (Grimont and Deval, 1982). Four somatic (O) and one flagellar (H) antigens were identified that defined four serovars. All American strains studied (isolated from the fig wasp or from a human patient) belonged to serotype O1:H1; strains from the Mediterranean region (Sicily, Tunisia, France) were not so antigenically uniform and all four serotypes were found in figs from Sicily.

An antigenic scheme for *S. rubidaea* has also been devised (Grimont et al., manuscript in preparation). Nine somatic and five flagellar antigens were identified. A total of 53 strains were distributed among 14 complete (O+H) serotypes.

Bacteriocin Typing of *Serratia marcescens*

Two different schemes have been developed for typing *Serratia marcescens* strains by susceptibility to bacteriocins ("marcescins"). The system of Traub (1980) was developed since 1971 (Traub et al., 1971) and uses marcescins (incomplete phage structures) produced by 10 selected strains. In 1980, 73 bacteriocin types had been described and about 93% of strains were typable (Traub, 1980). In this system, bacteriocin type 18 is often associated with serotype O6/14:H12 in multiple-drug-resistant nosocomial strains.

Farmer (1972b) independently developed another system of typing based on susceptibility to marcescins. After mitomycin induction, 12 bacteriocin-producing strains were selected, and the 12 marcescins could subdivide 93 strains into 79 types.

Typing of *S. marcescens* by production of bacteriocin was also developed by Farmer (1972a). Twenty-three strains susceptible to bacteriocins were selected to serve as indicator strains. Each unknown *S. marcescens* strain is treated with mitomycin, and the marcescin produced (if any) is identified according to the pattern of susceptibility demonstrated by indicator strains. This method could be used to type 91% of the strains studied.

Phage Typing of *Serratia*

Farmer (1975) has developed a phage typing system common to *Serratia marcescens*, *S. liquefaciens*, and *S. rubidaea* (*marinorubra*). With 74 phages, 95% of the *S. marcescens* strains and 50% of the *S. liquefaciens* and *S. rubidaea* strains could be typed. Phage typing was found to be convenient for subdividing prevalent serotypes (Negut et al., 1975). F. Grimont (1977) independently developed another phage typing system

for nosocomial strains isolated in Bordeaux. Most of these *S. marcescens* strains gave phage susceptibility patterns that corresponded to phage types described by F. Grimont (1977); however, strains isolated in other cities of France were less often typable, and strains received from other countries were rarely typable in this system.

Typing by Enzyme Electrophoresis

By using agar gel electrophoresis, Grimont et al. 1977a and Grimont and Grimont (1978c) detected seven different proteinases (called P₅, P₆, P₇, P_{9a}, P_{9b}, P₁₁, and P₁₂) produced by strains of *S. marcescens*. Each *S. marcescens* strain can produce one to four proteinases; 651 strains of *S. marcescens*, isolated over a period of six years in a French hospital, gave 33 different proteinase patterns (called zymotypes). However, six zymotypes alone accounted for 76% of the isolates. Proteinase electrophoresis was thus used as an epidemiological marker (Grimont and Grimont, 1978c).

Goullet (1978, 1981) showed that the *Serratia* species were characterized by distinct electrophoretic patterns of their esterases. However, these esterase profiles were not used as epidemiological marker.

Enzyme polymorphism among 99 *S. marcescens* isolates was determined by electrophoresis of nine enzymes (Gargallo-Viola, 1989). More than one electromorph was found for seven of these enzymes (alanine dehydrogenase, catalase, NADP-dependent malic enzyme, 6-phosphoglucate dehydrogenase, glucose-6-phosphate dehydrogenase, NADP-dependent glutamate dehydrogenase, and indophenol oxidase), and 33 distinctive electrophoretic types. One group was represented exclusively by isolates belonging to nonpigmented biotypes recovered almost entirely (97%) from clinical samples. The other group comprised all isolates belonging to a pigmented biotype. Electrophoresis of glucose-6-phosphate dehydrogenase alone can distinguish *S. marcescens* strains belonging to a pigmented biotype from those belonging to a nonpigmented biotype (Gargallo et al., 1987). A very good correlation was found between electrophoretic periplasmic protein patterns, enzyme electrophoresis, and biotyping by carbon source utilization (Gargallo-Viola and Lopez, 1990).

Restriction Patterns

Electrophoretic patterns of fragments produced after cleavage of total DNA by restriction endonucleases have been used to compare *S. marcescens* strains in epidemiological studies (McGeer et al., 1990).

A new, generally applicable typing method has recently been proposed by Grimont and Grimont (1986) in which the DNA restriction fragments carrying rRNA genes are visualized after hybridization with a labelled *E. coli* 16+23S rRNA probe (rRNA gene restriction patterns). Five to seven DNA restriction fragments (after digestion by *Bam* HI) or 11 to 13 fragments (after digestion by *Eco*RI) were observed with all *Serratia* strains tested (Grimont and Grimont, manuscript in preparation). The different *S. marcescens* biogroups display different rRNA gene restriction pattern. This method should be useful in resolving occasionally uncertain (or conflicting) results given by serotyping and biotyping.

The Genera *Proteus*, *Providencia*, and *Morganella*

JIM MANOS AND ROBERT BELAS

Introduction

The three genera *Proteus*, *Morganella* and *Providencia* presently comprise a total of ten species. All are motile, Gram-negative rods with peritrichous flagella, and are assigned to the *Enterobacteriaceae* family mainly on the basis of shared biochemical characteristics. Most significantly, they are characterized by their ability to oxidatively deaminate phenylalanine and, in most cases (except for some *Providencia* spp.), to hydrolyze urea (Farmer et al., 1977; Moltke, 1927; Wenner and Retger, 1919). Unusual features include the ability of *Proteus* sp. to differentiate into swarmer cells upon colonization of solid surfaces. This topic will be covered in more detail in ensuing sections.

Interest in the species comprising these genera has occurred mainly from a clinical perspective, as they include a number of significant human pathogens. In human disease, most infections are associated with prolonged hospitalization and in the case of *Proteus* and *Morganella* spp., colonization of indwelling catheters and associated urinary tract infections (UTIs).

Taxonomy and Phylogeny

Before the advent of phylogenetically based classification, an array of biochemical tests formed the basis for taxonomic classification of the genera *Proteus*, *Providencia*, and after its separation into a new genus, *Morganella*. Tables 1 and 2 list the major biochemical tests used to compare and differentiate between the genera. As shown in Table 1, the most significant shared characteristics are the (oxidative) deamination of phenylalanine and tryptophan; both are used to distinguish between these three genera and other *Enterobacteriaceae* that do not produce these deaminases. The tests for production of these deaminases were developed in the 1950s and still are widely used (Henriksen, 1950; Thibault and Le Minor, 1957). Table 2 shows the biochemical tests that are commonly used to distinguish between these genera. The only test that will dis-

tinguish *Morganella* from *Proteus* and *Providencia* is the lysine iron agar test. On the other hand, several tests will distinguish *Proteus* from *Providencia*. *Providencia* is characterized by the production of acid from a variety of sugars, whereas *Proteus* is distinguished from *Providencia* by the hydrolysis of gelatin and the production of lipase and hydrogen sulfide. The use of molecular phylogenetic methods of classification has resulted in several species being reassigned to separate genera based on relatedness at the DNA level. These changes include: the new genus *Morganella*, with transfer of the species *Proteus morganii* to it (Brenner et al., 1978); the classification of *Providencia alcalifaciens* biogroup 3 as the separate species (*Providencia rustigianii*; Higashitani et al., 1995); and the identification of a subgroup within the latter as a distinct species, *Providencia heimbachae* (Muller et al., 1986b).

Isolated in 1906 (Morgan, 1906), *Morganella morganii* was originally included in the genus *Proteus* as *Proteus morganii*. Brenner et al. (1978) showed that *P. morganii* had less than 20% homology to *Proteus* and *Providencia* spp., necessitating relocation into a new genus. The method employed by Brenner et al. in this reclassification compared the amount of single stranded ³²P-labeled DNA reassociating with DNA from the same source (homologous reaction), relative to the amount reassociating with DNA from other species in these genera. The resulting value was expressed as “percent DNA relatedness.” *Morganella morganii* has subsequently been subdivided into two subspecies based on its ability to ferment trehalose and the results of DNA-DNA hybridization studies (Jensen et al., 1992). *Morganella morganii* subsp. *morganii* is composed of four biogroups (A, B, C and D), and it does not ferment trehalose, though *M. morganii* subsp. *sibonii* contains three biogroups (E, F and G) and does ferment trehalose.

Further subdivision of these species is likely with the application of more discriminatory molecular methods of characterization. As an example, the use of molecular typing by 16S ribosomal RNA (rRNA) gene fingerprints (ribotyping) has recently demonstrated that, though

clinical isolates of *P. mirabilis*, *P. penneri*, *M. morganii* and *P. heimbachae* had identical ribotyping patterns to those of their respective type strains, those from the remaining species all exhibited heterogeneity, containing from two to four ribogroups each (Pignato et al., 1999). Thus it is possible that subdivision of members of these latter species into one or more subspecies may be considered appropriate in the future.

The genus *Proteus* presently contains four species: *P. mirabilis*, *P. vulgaris*, *P. penneri* and *P. myxofaciens*. *Morganella* has one species (*M. morganii*), whereas *Providencia* contains five species (*Providencia stuartii*, *Providencia rettgeri*, *P. rustigianii*, *P. heimbachae* and *P. alcalifaciens*; (Rozalski, 1997; Rustigian, R., and C. A. Stuart, 1945).

The 16S rRNA gene sequences of six representative species: *P. mirabilis*, *P. vulgaris*, *P. penneri*, *M. morganii*, *P. stuartii* and *P. rettgeri* were obtained and a phylogenetic tree constructed using the ClustalW alignment program (Thompson et al., 1994) and the tree-drawing program Phylodendron (Gilbert, D. G., 1989) to display the evolutionary relationships between the species in these genera. The tree (Fig. 1) indicates the close relationship between the two *Providencia* sp., as well as the similarity between two of the *Proteus* sp., *P. vulgaris* and *P. penneri*. The relationship between *P. mirabilis* and the *P. penneri*–*P. vulgaris* group is, however, more distant, a fact reflected in the horizontal distance between *P. mirabilis* and the other two *Proteus* sp. This greater distance at the 16S rRNA level between *P. mirabilis* and the other members of the genus *Proteus* may be a reflection of the phenotypic and physiological characteristics of *P. mirabilis*, which set it slightly apart from other members of the genus.

Electron micrographs of the six species, taken from overnight cultures grown in Luria-Bertani broth (LB; Ausubel et al., 1987), are shown in Fig. 2. Figure 2B is an electron micrograph of a *P. mirabilis* differentiated swarmer cell growing

Fig. 1. Unrooted phylogenetic tree of the 16S rRNA sequences from selected *Proteus*, *Providencia* and *Morganella* sp. The tree was derived using the ClustalW alignment program (Warren, J. W., 1987a) and the tree-drawing program Phylodendron (Fletcher, M. et al., 1994). The scale bar represents the expected number of changes per sequence position.

on Luria-Bertani agar (LBA). The cell elongation and hyperflagellation typical of this phenotype is clearly evident (see “Cell Differentiation and Swarming”).

The Genus *Proteus*

Habitat

Proteus mirabilis is the type species of the genus *Proteus* and by far the most extensively studied member of this genus. It was originally described and named by Hauser in 1885 for the Homer’s *Odyssey* character who “has the power of assum-

Fig. 2. Electron micrographs of selected species comprising the genera *Proteus*, *Morganella* and *Providencia*. ing different shapes in order to escape being questioned” (Hoeniger, 1964). Both *P. mirabilis* and *P. vulgaris* are widely distributed in the environment and have been isolated from the intes-

tinal tract of mammals, birds and reptiles. *Proteus mirabilis*, and to a lesser extent *P. vulgaris*, are common inhabitants of the human gastrointestinal tract. *P. mirabilis*, in particular, also

may colonize the urinary tract under certain circumstances, where it is considered an opportunistic pathogen and one of the principal causes of UTIs in hospital patients with indwelling urinary catheters.

Proteus vulgaris is also a common inhabitant of the human gut and a urinary tract pathogen; however, it is associated much less commonly with UTIs than *P. mirabilis*. For example, in a study of *Proteus* species found in urine from 217 hospital patients, Senior identified 258 strains of *P. mirabilis* compared to four strains of *P. vulgaris* (Senior, B. W., 1979).

Proteus penneri was first described as a species distinct from *P. vulgaris* in 1982 (Hickman et al., 1982). It has since been isolated from a number of diverse clinical sites, including abdominal wounds, urine samples, bladder calculi, epidural ulcers and bronchoalveolar lavage fluid (Krajden et al., 1984; Krajden et al., 1987; Latuszynski et al., 1998; Li et al., 1992).

The species *P. myxofaciens* has been isolated from both living and dead gypsy moth larvae (*Porthetia dispar*; Costas, M., et al., 1993). DNA/DNA hybridization studies and phenotypic similarity have formed the basis of its inclusion in the genus *Proteus* (Brenner et al., 1978). No further investigations have been reported on its characterization or pathogenicity in the host.

Isolation and Identification

The species comprising the genus *Proteus* are distinguished biochemically from *Morganella* and *Providencia* spp. by their production of hydrogen sulfide and lipase, hydrolysis of gelatin and a lack of acid production from mannose (Table 2; Penner, J. L., and J. N. Hennessy, 1979b). Optimum growth conditions for these bacterial species are obtained at 37°C, which reflects the intestinal niche occupied by many of these bacteria. When grown in liquid media, *Proteus* sp. appears as short rods with six to ten peritrichous

flagella (Fig. 2A). Most strains also can differentiate into elongated hyperflagellated cells during growth on solid surfaces such as LBA (Fig. 2B), leading to the surface translocation event known as “swarming” (see “Physiology”). Swarming behavior makes it difficult to isolate single colonies for further study; however, colony isolation on agar can be obtained through an increase in the agar concentration to 20 g/liter and the addition of 5 ml glycerol per liter of medium. This has the effect of slowing down or preventing the initiation of swarming, leading to the formation of discrete colonies (Belas, 1992).

The spot indole test has been evaluated by Bale et al. (1985) as a rapid method of distinguishing *P. mirabilis* from *P. vulgaris* (Bale et al., 1985). In this evaluation, the majority (95.7%) of *P. mirabilis* strains gave a negative spot indole result. The predictive value was greater than 99%, if only isolates representing single strains were used, whereas *P. vulgaris* isolates were 88.9% positive by this method. Differential culture media also has been developed for presumptive screening of *Enterobacteriaceae*, which in turn can distinguish between genera in this family, including *Proteus* sp. (Hawkey et al., 1986a; Houang, E. T., et al., 1999; Manafi and Rotter, 1991).

Physiology

CELL DIFFERENTIATION AND SWARMING. One significant phenotypic characteristic shared by members of the genus *Proteus* is the ability to transform into a distinctive “swarmer” cell when cultured on a solid agar-containing medium. Differentiation of *P. mirabilis* to the swarmer stage has been studied most extensively (Allison and Hughes, 1991; Belas, 1992; Williams and Schwarzhoff, 1978). When grown in liquid media, the cells exist as 1.5–2.0 µm rods with 6–10 peritrichous flagella. These so-called “swimmer” cells exhibit characteristic swimming and

chemotactic behavior, moving away from repellents and towards attractants (Allison et al., 1993; Lominski and Lendrum, 1947). Transfer of swimmer cells onto a solid growth medium, such as that containing agar, results in a remarkable physiological and morphological transformation of the bacteria. Shortly after contact with the surface, the swimmer cells begin to differentiate into a morphologically and biochemically unique cell known as “the swarmer cell” (Fig. 2B).

Swarmer cell differentiation and swarming behavior may be broken down into discrete steps. The first step in swarmer cell morphogenesis is cellular elongation, resulting from inhibition of the septation mechanism (Armitage et al., 1974). The molecular basis that underlies the inhibition of proper septum formation is not known, but may involve SufA (also known as “SfiA”) or other proteins known in *Escherichia coli* to adversely affect septum formation (Higashitani et al., 1995; Huisman and D’Ari, 1981; Huisman et al., 1984). Belas et al. (1995) analyzed several *P. mirabilis* mutants defective in swarming and many of these strains had defects in genes encoding proteins necessary for cell wall structure. Elongated swarmer cells are typically 60–80 μm in length and are polyploid, with the number of chromosomes per cell being roughly proportional to the increase in length. Concurrent with this, overexpression of the flagellin protein leads to the synthesis of hundreds to thousands of new flagella required for movement across the solid surface (Armitage and Smith, 1978; Hoeniger, 1965; Hoeniger, 1966; Houwink and van Iterson, 1950; Leifson et al., 1955). Diagrammatic representations of typical swimmer and swarmer cells are shown in Fig. 3, together with a summary of the main distinguishing features of the two cell types. These flagella are composed of the same flagellin subunit as the swimmer cell flagella, and in both cases flagellin is transcribed from the *flaA* gene, indicating that the same flagellar species is produced upon surface induction (Belas, 1994a; Belas and Flaherty, 1994b; Murphy and Belas, 1999).

Studies in *P. mirabilis* and in the swarming bacteria *Vibrio parahaemolyticus* and *Serratia marcescens* have shown swarmer-cell-specific genes are expressed when swimmer cells are transferred to solid media, suspended in highly viscous broths or agglutinated with antibody to the cell surface (Alberti and Harshey, 1990; Allison et al., 1993; Belas et al., 1986; McCarter et al., 1988; Stewart et al., 1997). All of these conditions result in inhibition of flagellar rotation, leading to the conclusion that the flagella act as tactile sensors of the external environment.

Swarmer cell differentiation and swarming behavior are inextricably linked, but a differentiated swarmer cell by itself is unable to swarm

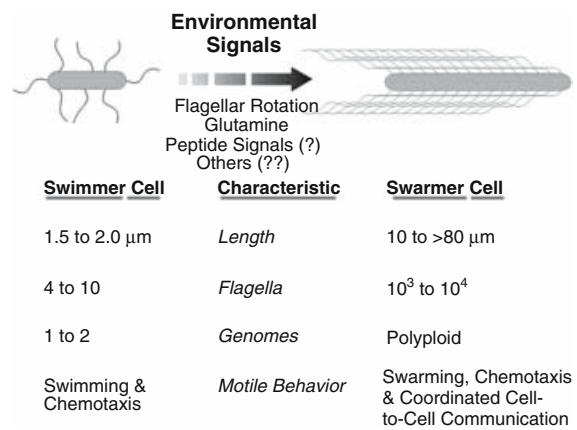

Fig. 3. The characteristics of *P. mirabilis* swarmer cell differentiation and swarming motility. Swarmer cell differentiation is controlled through a combination of sensing environmental conditions that reduce wild-type flagellar filament rotation and reacting to a specific chemical stimulus, the amino acid glutamine. The swarmer cell is characterized by an elongated polyploid cell that synthesizes numerous flagella in response to the aforementioned signals.

across a nutrient agar surface. Rather, swarming behavior is a cell-cell contact event that requires intimate contact and interaction between groups of swarmer cells to coordinate their movements (Bisset, 1973a; Bisset, 1973b; Bisset and Douglas, 1976; Brogan et al., 1971; Douglas and Bisset, 1976; Douglas, 1979). The arrangement of the coordinated swarmer cells during migration is illustrated in Fig. 4.

An important aspect of the *P. mirabilis* swarming colony pattern is its cyclic nature. As shown in Fig. 5, each cycle can be broken down into four parts, 1) swarmer cell differentiation, 2) the lag period prior to active movement, 3) swarming colony migration and 4) consolidation (where the cells stop moving and dedifferentiate back to swimmer cell morphology). During the migration phase, the fully differentiated swarmer cells move outward in unison in all directions from the original site of inoculation for a period of several hours. Movement then ceases and a process referred to as consolidation takes place (Bisset, 1973a; Bisset, 1973b; Hoeniger, 1964; Hoeniger, 1965; Hoeniger, 1966; Hoeniger and Cinitis, 1969; Williams and Schwarzhoff, 1978), during which the swarmer cells dedifferentiate back into swimmer cells. After a period in this stage, the swarming phase recommences and proceeds until the next consolidation phase. The cycle of swarming and consolidation is then repeated several times, until concentric rings, formed by the swarming bacteria and delineating the phase changes, cover the agar surface (Fig. 7). The purpose of the consolidation phase has yet to be fully elucidated; however, recent work by Matsuyama et

Fig. 4. The mechanics of swarming in *P. mirabilis* and the requirement for cell-cell contact. The micrograph (top) shows a finger-like projection of *P. mirabilis* swarmer cells migrating across a solid surface. The cartoon (bottom) demonstrates the arrangement of swarmer cells during coordinated motion across a solid surface. Individual cells are interlinked into groups and move en masse away from the point of inoculation, with the flagella from all cells in the group moving in unison. The arrows point in the direction of movement.

al. (2000) showed that the time course of this phase is unaffected by replica plating of the swarm edge. This indicates that consolidation is not a consequence of nutrient and metabolite changes in the medium. Figure 6 contains four video segments detailing the events associated with swarming at the microscopic level. Figure 7 shows swarming behavior during colony development and bulls-eye ring formation.

THE INFLUENCE OF SIGNAL TRANSDUCTION IN SWARMING. Swarming is, by

its very nature, a surface-associated and cell-density-dependent phenomenon. Individual *P. mirabilis* cells rely on their ability to sense the surrounding environment and use these cues to trigger the development of the swarmer cell, as well as to coordinate movement of the swarm across the surface. One way this information is acquired is through monitoring the rotation of the flagella to initiate cellular differentiation (see “Cell Differentiation and Swarming”). Other methods include cell-to-cell contact with neighboring bacteria to aid in movement, the chemotactic sensing of nutrients and repellents in the external medium, and possibly through a density-dependent sensing of cell population density known as “quorum sensing.” We will discuss each of these signal transduction mechanisms in turn in the next paragraphs.

Research into the relationship between chemotaxis and swarming in *P. mirabilis* (Belas et al., 1991a; Williams and Schwarzhoff, 1978) has preceded that into the relationship between chemotaxis and other swarming bacteria. Early work suggested that chemotaxis did not play a major role in the differentiation to the swarming phenotype (Williams et al., 1976). However, later studies demonstrated that nonswarming mutants of *P. mirabilis* produced by transposon insertion also exhibit deficiencies in chemotactic response (Belas et al., 1991b), suggesting that chemotactic signal transduction is important for swarming. Further work by Allison et al. (1993) has shown that the amino acid glutamine induces differentiation to the swarmer cell in *P. mirabilis* by acting as a chemoattractant. This effect may work at the level of transcription, because when glutamine is added to a defined, nonswarming medium, expression of the *flaA* (flagellin) and *hpmA* (hemolysin) genes in *P. mirabilis* increases 40-fold. The viscosity of the growth medium also affects swarming, with the addition of 3% v/v polyvinylpyrrolidone (PVP) to liquid chemotaxis medium resulting in increased attraction to glutamine. Attempts to repeat these experiments in other laboratories using different strains of *P. mirabilis* have been unsuccessful, raising doubts as to whether all *P. mirabilis* strains respond to glutamine by swarming. In other swarming members of the *Enterobacteriaceae*, Harshey and Matsuyama (1994) reported a link between chemotaxis and the swarming of *E. coli* and *Salmonella typhimurium* on specific (Eiken) agar.

Quorum sensing is the ability of a bacterial population to monitor its density through expression of small extracellular signaling molecules referred to as “autoinducers.” Quorum sensing was first identified and characterized in the luminescent marine bacterium *Vibrio fischeri* wherein bioluminescence is controlled by cell density and autoinducer signal transduction

Fig. 5. The cyclic nature of *P. mirabilis* swarming behavior. Inoculation of *P. mirabilis* swimmer cells onto a solid nutrient surface such as Luria-agar induces the expression of swarmer-cell specific genes, leading to differentiation into the swarmer cell and migration away from the site of inoculation. This process is interspersed with periods of consolidation and dedifferentiation back into the swimmer cell morphology.

(Eberhard, 1972; Eberhard et al., 1981; Nealson, 1977). The signal molecule, or autoinducer, is often a homoserine lactone with an *N*-acyl chain of variable length. In the case of *V. fischeri*, *N*-acylhomoserine lactone (AHL) can freely per-

meate the membrane and accumulate inside the cell until an optimum concentration is reached, whereupon it binds to a specific receptor and initiates activation of the bioluminescence genes (Kaplan and Greenberg, 1985). The specific receptors for the AHL signal are members of the LuxR family of transcription regulators. Two genes, *luxR* and *luxI*, were originally identified in *V. fischeri* as essential regulators of the AHL signaling system, and homologs of these have subsequently been identified in other Gram-negative bacteria (Stevens and Greenberg, 1998). In pathogenic bacteria such as *Pseudomonas aeruginosa*, AHL-mediated quorum sensing is involved in the regulation of multiple virulence determinants, including exoproteases, lipases and exotoxins, suggesting that a critical bacterial concentration must be attained for the deployment of its virulence factors (Parsek and Greenberg, 2000; Telford et al., 1998).

Fig. 7. Development of the bull's-eye rings of *P. mirabilis* colonies. (A–C) Sequential photographs of L-agar inoculated in the center with 5 ml of *P. mirabilis* swimmer cells and incubated at 30°C for 4 h (A), 24 h (B) and 48 h (C). (D) Video recording in time lapse showing swarming of *P. mirabilis* across the solid surface of an L-agar plate, taken over 24 hours of growth at 30°C and 80% humidity. For the video, see the online version of *The Prokaryotes*.

In *Serratia liquefaciens*, another swarming member of the *Enterobacteriaceae*, *S. liquefaciens*, Eberl et al. (1996) have demonstrated that initiation of swarmer-cell differentiation involves diffusible signal molecules that are released into the growth medium. In particular, the autoinducer *N*-acylhomoserine lactone (AHL) is required for swarming motility in this species

(Givskov et al., 1998; Lindum et al., 1998). The AHL derivatives *N*-butanoyl-L-homoserine lactone (BHL) and *N*-hexanoyl-L-homoserine lactone (HHL) were identified by Eberl et al. (1996) in cell-free *S. liquefaciens* culture supernatants.

The *swrI* (swarmer initiation) gene, whose predicted translation product exhibits substantial homology to the LuxI family of putative AHL synthases, is responsible for directing synthesis of both BHL and HHL (Eberl et al., 1996). Further work by this group since has shown that the coordinate expression of *swrI* and the flagellar master operon *flhDC* is required to initiate swarming motility in *S. liquefaciens* (Eberl et al., 1999; Givskov et al., 1998; Lindum et al., 1998).

Attempts to prove the existence of an AHL-type autoinducer in *P. mirabilis* have been unsuccessful; however, evidence exists that this bacterium may utilize an alternate method of density-dependent quorum sensing. Belas et al. (1998) have characterized a gene that upon mutation decreases the length of the lag phase prior to swarming. This gene, referred to as “*rsbA*” (for regulator of swarming behavior) encodes a sensory protein displaying similarity to LuxQ and other bacterial histidine kinases of the two-component regulatory superfamily of bacterial response regulators that perform functions required for a second density-sensing system (Bassler et al., 1994; Freeman and Bassler, 1999; Lilley and Bassler, 2000). This finding suggests that RsbA may function as a sensor of environmental conditions required to initiate swarming.

Ecology

Both *P. mirabilis* and *P. vulgaris* are members of the normal flora of the mammalian intestinal tract and have been isolated from humans, dogs, monkeys, pigs, sheep, cattle, raccoons, cats, rats and other mammals. They also are distributed widely in the environment, with reservoirs in soil, water, sewage and feces (Guentzel, 1991). Other species of *Proteus* are less widely distributed. For example, *P. penneri* is absent from the intestines of livestock (Hawkey et al., 1986b), whereas *P. myxofaciens* is confined to the larvae of the gypsy moth (Cosenza and Podgwaite, 1966).

Epidemiology

Owing to their varied habitats, members of the genus *Proteus* and related genera have many possible routes of human infection. The modes of transmission may include nosocomial sources, such as hospital food and equipment, intravenous solutions and human contact through contaminated skin surfaces. Long-term indwelling catheters are a prime site of colonization and

infection for *P. mirabilis* and *P. vulgaris* (Kunin, 1989; Stickler and Hughes, 1999; Warren, 1987a).

Serological typing of *P. mirabilis* and *P. vulgaris* traditionally has been done using the slide agglutination test and the indirect hemagglutination test (Gmeiner et al., 1977; Schmidt et al., 1970). Previously, the Dienes test, in which swarming *Proteus* strains were inoculated on nutrient agar and allowed to swarm into one another, was used to distinguish between strains of these species. If a distinct line of demarcation (a Dienes line) occurred at the junction between the strains, they were considered different (Dienes, 1946). This method has fallen out of favor because of the difficulties associated with interpreting the results.

Other bacteriological typing methods also have been used, including biotyping, bacteriophage typing, and typing schemes using both bacteriocin production and bacteriocin sensitivity (Anderson and Engley, 1978; Hickman and Farmer, 1976; Kusek and Herman, 1980; Schmidt and Jeffries, 1974). In a comparative study by Kusek (1981), five bacteriological typing methods were assessed for their ability to differentiate 100 clinical isolates of *P. mirabilis*. The highest sensitivity and specificity was obtained using bacteriocin production typing, which yielded 29 distinct bacteriocin types among the 80% of strains that were typable (Kusek and Herman, 1981). Bacteriophage typing sets also have been tested as tools for differentiation of *Proteus* strains; however, a more diverse set of phages is needed to adequately differentiate between as many strains as possible (Sekaninova et al., 1994; Sekaninova et al., 1998).

Modern molecular methods employing the polymerase chain reaction (PCR) to produce DNA fingerprints and other 16S ribosomal RNA gene (ribotyping) methods of strain differentiation have been applied to distinguish *P. mirabilis*, *P. vulgaris* and *P. penneri* strains (Costas et al., 1993; Hoffmann et al., 1997; Hoffmann et al., 1998; Serwecinska et al., 1998). Hoffmann et al. (1998) compared four typing methods (including plasmid profiles, outer-membrane-protein profiles, randomly amplified polymorphic DNA PCR [RAPD-PCR], and restriction fragment length polymorphism [RFLP] on strains of *P. penneri* and found that RAPD-PCR alone, with one of two random primers, revealed 13 reproducible typeable patterns (Hoffmann et al., 1998). Thus, the RAPD method, essentially a DNA fingerprinting method using arbitrary primers (Akopyanz et al., 1992), revealed a significant DNA diversity among *P. penneri* strains that was not detected by other methods (Hoffmann et al., 1997; Hoffmann et al., 1998). The RAPD-PCR technique has the advantage of being quick and economical, with high reproducibility and typability; however, the choice of primers is critical to

obtaining discriminating results (Madico et al., 1995).

Pathogenicity

The incidence of UTI involving *P. mirabilis* or *P. vulgaris* is lower than that for *E. coli*; however, *P. mirabilis* infections are more likely to be long-term and persistent, and to lead to greater complications threatening the patient's health than those involving *E. coli* (Mobley and Warren, 1987). The majority of *Proteus* infections are associated with prolonged hospitalization and the complications of long-term urinary catheterization. The complications that can result from *Proteus* UTI include catheter and urinary tract obstruction, kidney stone formation (urolithiasis), pyelonephritis, fevers and bacteremia (Mobley and Warren, 1987; Rubin et al., 1986; Senior, 1983; Story, 1954; Warren et al., 1987b). In serious cases of *Proteus* UTI, chronic renal inflammation, vascoureteral reflux and renal failure are frequently observed (Cohen and Preminger, 1996; du Toit et al., 1995; Warren, 1987a). The sites of UTI and the respective complications resulting from infection at these sites are shown in Fig. 8, whereas Fig. 9 provides a breakdown of the causes of *P. mirabilis* UTI.

VIRULENCE FACTORS. At least ten virulence factors potentially contributing to the pathogenicity of *Proteus* sp. have been identified. The majority of these virulence factors, with the exception of the fimbriae, are expressed during swarmer cell differentiation and swarming behavior. These virulence factors can be divided into two groups: 1) proteins, enzymes and other secreted products, and 2) surface structures. In terms of their relevance to pathogenesis, the most significant virulence factors (in order of importance) are: urease, ZapA (a protease that specifically degrades immunoglobulins IgA and IgG), lipopolysaccharide, outer-membrane proteins, and hemolysin. The most significant surface structures, in order of importance to pathogenesis, are the flagella and associated swarming phenotype of *P. mirabilis* and *P. vulgaris*, and several types of fimbriae, including: mannose-resistant *Proteus*-like fimbriae (MR/P), mannose-resistant *Klebsiella*-like fimbriae (MR/K), *P. mirabilis* fimbriae (PMF), nonagglutinating fimbriae (NAF), and an uncharacterized fimbrial type with a 24-kDa major subunit (also referred to as "F24"). The potential of these virulence factors in *Proteus* to cause disease has been a prime area of study and the major conclusions in each case are presented here.

Urease. Urea is a by-product of nitrogen metabolism that is ubiquitous in a wide range of eukaryotes and prokaryotes. The enzyme urease breaks down urea to ammonia and carbon dioxide. These end products have the effect of

Fig. 8. The human urinary tract, showing the sites of *P. mirabilis* infections, hence the diseases resulting from infection, and the virulence factors associated with pathogenesis of disease at the respective sites (see “Pathogenicity”).

Fig. 9. The causes of *P. mirabilis* urinary tract infections (UTI) in humans, compiled using epidemiological data from hospitalized patients. Adapted from Mobley and Warren (1987).

increasing the pH, which in turn augments the survival of bacteria such as *Helicobacter pylori* to create a less acidic environment that may be more suited for colonization (Gomez-Duarte et al., 1998; Kuwahara et al., 2000; Lee et al., 1999). In other microbes, ureases play an important role in utilization of environmental nitrogenous compounds and urea-based fertilizers. At the same time, the production of urease by *P. mirabilis* and *P. vulgaris* may contribute to the development of urinary stones and pyelonephritis, as mentioned earlier. This is one possible reason why *Proteus* infections cause more cytological damage than *E. coli* infections (Cohen and Preminger, 1996; du Toit et al., 1995; Johnson et al., 1993; Mobley and Hausinger, 1989).

Early studies using *P. mirabilis* treated with urease inhibitors established a link between urease and colonization of rat urinary tracts. In

these studies, the renal tissue of control-infected rats contained a far higher number of bacteria and had greater tissue damage than did those of rats infected with inhibitor-treated *P. mirabilis* (Musher et al., 1975). Further evidence of the role played by urease in *P. mirabilis* pathogenesis has been demonstrated by comparative histological examination of renal tissues postinfection by either the wild type, parental strain, or an isogenic urease-negative mutant using a mouse model of ascending UTI (Johnson et al., 1993; Jones et al., 1990). Mice challenged with the isogenic urease mutant developed significantly less bacteriuria and urinary stones compared to the parent strain. The parent strain also showed greater persistence in the bladder and kidney than did the strain lacking urease (for reference to sites of infection, see Fig. 8).

IgA and IgG Proteases. Secretory immunoglobulins of the IgA class are produced by mucous tissue and are particularly resistant to enzymatic breakdown by proteases. The ability to degrade a host's secretory IgA may provide a microorganism with an advantage by evading the host immune response, thus gaining valuable time for the bacterium to establish a foothold for colonization. Many pathogenic bacteria that invade mucosal tissues, such as the epithelial lining of the intestine and urogenital tract, have potent, extracellular IgA-degrading proteases, whereas nonpathogenic counterpart species in the same genus often do not. For example, pathogenic species of *Neisseria*, such as *N. gonorrhoeae* and *N. meningitidis*, possess IgA-degrading proteases, though nonpathogenic species (including *N. lactamica* and *N. sicca*) do not (Kilian et al., 1983). The possession of IgA protease by certain members of this genus may thus be critical in providing these bacteria with an advantage to overcome the host humoral immune response during infection.

A protease capable of degrading two IgA subclasses (IgA1 and IgA2) as well as IgG has been identified in *P. mirabilis* (Loomes et al., 1990; Milazzo and Delisle, 1984; Senior et al., 1987b). Subsequent work by Wassif et al. (1995) has resulted in the characterization of this protease (referred to as “ZapA” and encoded by the *zapA* gene) as a metalloprotease of ca. 50 kDa. To investigate whether *zapA* expression correlates with another known virulence-enhancing phenomenon, swarmer-cell differentiation (see “Flagella and swarming”), Walker et al. (1999) measured the expression of *zapA* during swarmer-cell differentiation. The data obtained suggest that *zapA* expression is tightly coordinated not just with swarmer-cell differentiation, but with swarming behavior as well. Also, ZapA proteolysis is not essential for swarming, because ZapA⁻ strains were shown to produce wild-type swarmer cells and swarming colonies.

Both *P. vulgaris* and *P. penneri* also have been reported to possess IgA proteases. In a survey of protease production amongst 24 *P. vulgaris* strains, Senior et al. (1988) found that half of them produced IgA protease. Each of five of the *P. penneri* strains surveyed in the same study also produced IgA protease. Subsequent purification and comparative analysis of IgA protease from *P. mirabilis*, *P. vulgaris* and *P. penneri* showed that they shared similar electrophoretic patterns on sodium-dodecyl-sulfate polyacrylamide gel electrophoresis (SDS-PAGE) gels, with only slight differences in protein band mobility (Loomes et al., 1992).

Lipopolysaccharide and Outer-Membrane Proteins. During infection, bacterial lipopolysaccharide (LPS) is a primary target antigen (O-antigen) for host immunologic responses. Bacterial LPS activates macrophages to produce toxic oxygen radicals, interleukin-1 and tumor necrosis factor, leading to a wide range of effects in the host, including hypertension, fever and lethal shock (Hamilton and Adams, 1987; Rietschel et al., 1994). By way of example, the effect of *P. mirabilis* LPS on pig blood platelets is akin to that of thrombin (a strong platelet agonist), stimulating the enzymatic cascade leading to platelet aggregation (Wachowicz et al., 1998).

The outer membrane of Gram-negative bacteria contains several major proteins that are complexed with other membrane components such as LPS and phospholipid. The polysaccharide chains of the different species of *Proteus* LPS contain sufficient structural differences to result in an antigenically heterogeneous genus. These differences have been used to cluster *P. mirabilis*, *P. vulgaris*, and *P. penneri* strains into serogroups based on their agglutination when mixed with antibodies directed against specific species of LPS molecules (Kotelko, 1986; Penner and Hennessy, 1980a; Perch, 1948; Zych and Sidoreczyk, 1989). Certain LPS epitopes have been investigated to determine their role in antigenic specificity. The particular groups on the oligosaccharides found to play a dominant role in the specificity of *P. mirabilis* and *P. penneri* LPS are the amide of D-galacturonic acid with L-lysine α -D-GalA-(L-Lys) (and the amide of D-galacturonic acid with L-threonine α -D-GalA-[L-Thr]), respectively (Radziejewska-Lebrecht et al., 1995; Sidoreczyk et al., 1995).

Specific *P. mirabilis* outer-membrane proteins (OMPs) have been the targets of study with respect to their effects on the host immune response. One particular 39-kDa major OMP of *P. mirabilis* (subsequently identified as "OmpA") has been shown to greatly enhance the host IgG response for LPS in mice when complexed to LPS (Karch and Nixdorff, 1981; Karch and Nixdorff, 1983). Also, LPS is an activator of mac-

rophages, another important component of the host immune response, through their production of toxic oxygen radicals, interleukin-1 and tumor necrosis factor (Guthrie et al., 1984). Weber et al. have shown that OmpA inhibits the LPS-induced oxidative response and interleukin-1 production of murine macrophages when complexed to LPS, thus acting as a modulator of the interaction of LPS with macrophages (Weber et al., 1992; Weber et al., 1993).

Hemolysin. Bacterial hemolysins are frequently involved in the destruction of erythrocytes during infection and have been shown to contribute to the invasiveness and pathogenicity of several bacterial species (Braun and Focareta, 1991; Braun et al., 1993; Goebel et al., 1988; Menestrina et al., 1995). The importance of hemolysin in the virulence of *E. coli* was demonstrated through the isolation, cloning and transfer of hemolysin genes from virulent strains to avirulent ones (Hacker et al., 1983; Welch et al., 1981).

The association between hemolysin and virulence in *Proteus* sp. has proved more difficult to establish. Hemolytic activity is the least significant virulence factor in strains of *P. mirabilis* recovered from the CBA mouse model of ascending UTI (Fig. 10). However, early work by Peerbooms et al. (1985) showed a correlation between the hemolytic activity of *P. mirabilis* and its virulence in mice (Peerbooms et al., 1983). Hemolytic strains of *P. mirabilis*, *P. vulgaris* and *P. penneri* demonstrated markedly greater invasiveness of human and sheep erythrocytes in

Fig. 10. The major virulence factors of *P. mirabilis* and their influence on urinary tract pathogenesis using the CBA mouse model of ascending UTI. Data are represented as percent survival of each isogenic mutant strain compare to the survival of wild-type parental strain postinfection in the CBA mouse model of UTI. Adapted from Mobley and Warren (1987).

vitro in work by Rozalski and colleagues (Rozalski et al., 1986; Rozalski and Kotelko, 1987).

At the molecular level, the hemolysin structural genes (*hlyA* and *hlyC*) and the principal secretion gene (*hlyB*) of *E. coli* can be functionally complemented by the homologous genes from *P. mirabilis*, *P. vulgaris* and *M. morganii*, suggesting a functional relatedness between the three components in the two species. A second *E. coli* secretory gene (*hlyD*) is present in *P. vulgaris* and *M. morganii*, but absent from *P. mirabilis* (Koronakis et al., 1987; Koronakis and Hughes, 1988a; Koronakis et al., 1988b). The *E. coli* *hlyD* gene is required for secretion of hemolysin (Pimenta et al., 1999). This finding may explain why the secreted hemolytic activity of *P. mirabilis* remains cell-associated rather than being released into the surrounding medium. This possibility has been supported by subsequent investigations showing that the secreted hemolysin (HpmA) of *P. mirabilis* and *P. vulgaris* is genetically distinct from that of *E. coli* (Swihart and Welch, 1990b; Welch, 1987). *Proteus mirabilis* HpmA is cytotoxic for a variety of cell lines, including cultured human renal proximal tubular epithelial cells (Mobley et al., 1991; Swihart and Welch, 1990a). As mentioned above, colonization by isolates showing hemolysin activity forms by far the greatest proportion of *P. mirabilis* isolates recovered from the urine, kidneys and bladder of CBA mice with UTI (Fig. 10; Mohr O'Hara, C., et al., 1999). However, HpmA activity in such clinical isolates does not appear to be crucial to the development of pathogenesis (Mobley and Chippendale, 1990). Thus, hemolysin is not considered as important a virulence factor in *P. mirabilis* pathogenesis as flagella or urease (Mobley and Belas, 1995). In the case of *P. vulgaris*, hemolysin production, measured as hemolytic titer (Peerbooms et al., 1983), was found by Peerbooms et al. (1985) to be significantly lower than that for *P. mirabilis*, thus reducing the relevance of hemolysin in UTI for this species.

STRUCTURES INVOLVED IN THE VIRULENCE OF *PROTEUS* SP. Flagella and Swarming. It is generally accepted that flagella and swarming behavior play some role in the pathogenicity of *P. mirabilis*, and several studies support this hypothesis. For example, in work by Allison et al. (1992) using two different human uroepithelial cell lines (EJ/28 and 5637) and *P. mirabilis* mutants lacking flagella (Fla⁻), the loss of flagella resulted in a noninvasive bacterium when compared to the wild-type parent. In the same study, the ability to invade the EJ/28 and 5637 cell lines was closely identified with differentiated swarmer cells, which were 15-fold more invasive than undifferentiated swimmer cells. In vivo studies using a mouse model of UTI, Mobley et

al. (1996) reported a 100-fold lower recovery of a Fla⁻ mutant defective in flagellar filament synthesis when compared to the parent strain. While nonflagellated strains are less invasive, flagella do not appear to be absolutely required for virulence. Zunino et al. (1994) have found that a naturally occurring nonmotile strain could infect mice and cause UTI, whereas Legnani-Fajardo et al. (1996) reported similar results with an isogenic mutant lacking flagella.

The differentiated swarmer cell (see "Physiology") probably provides *P. mirabilis* and other swarming species such as *V. parahaemolyticus* with the advantage of rapid colonization during pathogenesis. Apart from the benefits of motility and adherence due to hyperflagellation, swarmer cell differentiation in *P. mirabilis* coincides with increased expression of several virulence factors (see "Virulence Factors") and has been linked to the expression of extracellular (capsular) polysaccharide. Evidence for this has been provided in studies by Gygi et al. (1995) utilizing transposon mutagenesis of a gene coding for a cell surface (capsular) polysaccharide in *P. mirabilis*. The mutants clearly showed retardation in translocation velocity across solid media and were attenuated in their ability to establish UTI in mice (Allison et al., 1994; Gygi et al., 1995).

Fimbriae. Collectively, the different species of fimbriae, which can be distinguished from flagellae by their shorter "spiked" appearance (Fig. 2C) are important in the attachment of the bacteria to the epithelial cell surfaces and colonization of the surrounding tissues (Silverblatt, 1974). Fimbriae appear to be differentially expressed at particular stages of the swarming cycle (Fig. 5) and are absent on hyperflagellated swarmer cells (Hoeniger, 1965; Latta et al., 1999). *Proteus mirabilis* produces MR/P, MR/K, NAF and PMF fimbriae (Adegbola et al., 1983; Bahrani et al., 1993a; Bahrani et al., 1993b). Both MR/P and MR/K fimbriae also have been shown to function as hemagglutinins and are highly immunogenic.

Mutants defective in the synthesis of various fimbrial species have been used to assess the role of each fimbrial type during *P. mirabilis* UTI. In particular, MR/P mutants (MrpA⁻) have been constructed by allelic exchange and are between 6 and 28-fold less efficient in colonizing mouse urinary tracts than the parental strain of *P. mirabilis* (see also Fig. 10). This result is supported by histopathology results showing less damage to the uroepithelium and no signs of pyelonephritis during colonization by Mrp⁻ strains (Bahrani et al., 1994). In studies on PMF fimbriae, isogenic PmfA⁻ mutants were found to colonize the bladder at lower levels than the wild-type parent, but bacterial colonization of the kidney was not affected by loss of this fimbrial type (Massad et al., 1994). The involvement of NAF fimbriae in bacterial adherence also has been demonstrated

in *P. mirabilis* strains that express NAF as their only fimbrial species. These studies have shown that NAF provide strong adherence to a number of mammalian cell lines in vitro, including uroepithelial cells (Latta et al., 1998; Tolson et al., 1995; Tolson et al., 1997). While it would appear that the production of fimbriae offers the bacterium a distinct advantage for survival in colonizing host tissues, one of the disadvantages of fimbriae to the potential colonizer is that they render the bacteria more susceptible to phagocytosis (Silverblatt and Ofek, 1978). Furthermore, the presence of fimbriae does not equally enhance adherence to all cell types. For example, the use of MR/P fimbrial mutants (*mrpA*⁻) in the CBA mouse model of ascending UTI has shown that the loss of MR/P fimbrial expression does not completely prevent colonization of renal tissue in *P. mirabilis* (Bahrani et al., 1994).

The Genus *Morganella*

Habitat

The sole species in this genus, *Morganella morganii*, is a commensal organism that can rapidly colonize the host gut with an accompanying hypertrophy of Peyer's patches and development of specific IgA responses in the lamina propria cells (Shroff et al., 1995). Strains of *M. morganii* also are known to infect the human urinary tract, respiratory system and blood, though they have only been recovered occasionally from these sources (Braunstein and Tomasulo, 1978).

Isolation and Identification

Isolation of *M. morganii* is accomplished using media for the routine isolation of *Enterobacteriaceae*. Enrichment media for culturing *M. morganii* from fecal specimens frequently include tetrathionate and selenite, which are added to nutrient broth (Rustigian and Stuart, 1945). The biochemical tests used to identify and distinguish *M. morganii* are shown in Table 2. It should be noted that although *M. morganii* is urease and indole positive, it does not swarm and is negative for most of the biochemical reactions characteristic of the *Proteus* spp.

The isolation of atypical *M. morganii* strains whose characteristics differ from those listed in Table 2 has resulted in the creation of a number of distinct biogroups that subdivide the species. Hickman et al. (1980) described 19 strains that were lysine positive and fermented glycerol within 24 h, in contrast to the type strain of *M. morganii*, which is lysine negative and ferments glycerol slowly or not at all. Another group of 14 *M. morganii* strains was found to be ornithine negative, whereas the type strain is ornithine positive. Because both groups were closely

related to *M. morganii* by DNA-DNA hybridization, they were considered distinct biogroups. There are currently seven recognized biogroups, based on ornithine and lysine decarboxylase reactions; however, some strains may carry plasmid-borne genes that code for these enzymes (Cornelis et al., 1981). Other phenotypes also have been used to distinguish the various biotypes. Janda et al. (1996) found resistance to the antibiotic tetracycline to be a useful distinguishing characteristic in their classification of 73 strains of *M. morganii* principally recovered from routine clinical specimens. The future subdivision of *M. morganii* into two or more species based on differences between biotypes remains a distinct possibility as more characteristics are used to distinguish between the biotypes.

Ecology

Morganella morganii occurs in low numbers in the feces of healthy humans and animals, including dogs, cattle and chickens (Hawkey et al., 1986b; Phillips, 1955; Prasad and Pandey, 1966; Tanaka et al., 1995). Its habitat may be more far-reaching, as *M. morganii* strains have been isolated from snakes, chickens suffering from respiratory disease, and ocular lesions of harbor seals and elephant seals (Lin et al., 1993; Muller, 1972; Thornton et al., 1998). It is unclear whether *M. morganii* was the causative agent in these diseases or an opportunistic colonizer of the previously diseased tissue.

Epidemiology

The incidence of *M. morganii* in diarrhea has been studied by Muller (1986a). In this study of fecal specimens from diarrheal and non-diarrheal patients, Muller isolated *P. mirabilis* and *M. morganii* more frequently from human diarrheal cases than from the stools of healthy individuals. These results agree with the data from earlier studies that showed a similar pattern of *M. morganii* recovery from diarrheal patients (Ahren, 1990; Das, 1996).

Epidemiological typing schemes have been developed for *M. morganii* based on the bacterial somatic and flagellar (O and H, respectively) antigens (Penner and Hennessy, 1979b; 1979d; Rauss and Voros, 1959; Rauss and Voros, 1967a; Rauss and Voros, 1967b; Rauss et al., 1975). The typing of *M. morganii* strains using the lytic activity of bacteriophages has been investigated in detail by Schmidt and Jeffries (1974). Seven phages were isolated from three *M. morganii* strains and these phages were successfully used to differentiate 13 of the 19 *M. morganii* strains in the study. Furthermore, lytic patterns remained stable in randomly selected *M. morganii* isolates retested several weeks later. While

phage typing is no longer widely used in the United States, these methods are still in favor in many East European countries.

A bacteriocin (referred to as “morganocin”) typing scheme for *M. morganii* based on production of and sensitivity to the protein has been described by Senior (Senior, 1987a). A total of 160 *M. morganii* strains were tested for sensitivity to morganocin and classified according to morganocin production and sensitivity. Most strains (97.5%) were sensitive to several different types of morganocins. Subsequent typing studies found that a combination of three distinct methods (bacteriocin typing, O-antigen serotyping and protein profiling) could be used to achieve a much greater degree of strain discrimination, especially inasmuch as protein profiling appears to be independent of O-serotype and bacteriocin type (Senior and Voros, 1989; Senior and Voros, 1990).

Pathogenicity

While the etiological role of *M. morganii* in diarrhea has not yet been firmly established, it is consistently recovered from the feces of diarrheal patients suggesting an involvement in the disease. Furthermore, some researchers have found *M. morganii* to be the sole potentially pathogenic bacterial species in the feces of diarrheal patients, thus strengthening its claim to being the cause of the disease in these cases (Rauss, 1936; Senior and Leslie, 1986).

In spite of the involvement of *M. morganii* in diarrheal disease, this species is less likely to be the causative agent of human UTI than *P. mirabilis*. This is mainly due to the slower growth rate of *M. morganii* in urine compared to that of *P. mirabilis* and the noninducible nature of its urease (Senior, 1983). Although not a major contributor to human UTI, *M. morganii* has been implicated in outbreaks of septicemia and bacteremia in humans and animals (Bagel and Grossman, 1985; Barragan Casas et al., 1999; Heard et al., 1988; McDermott and Mylotte, 1984; Novak and Seigel, 1986; Rowen and Lopez, 1998). *Morganella morganii* bacteremia most commonly occurs in postoperative patients who receive β -lactam antibiotics. McDermott and Mylotte (1984) investigated the case histories of 19 documented episodes of *M. morganii* bacteremia in 18 hospital patients and showed that the majority of infections were either postoperative or had associated wound injuries. They concluded that *M. morganii* is an infrequent cause of bacteremia and its presence in blood cultures may be an indicator of an environment, such as surgery, that is conducive for an outbreak of nosocomial infection.

VIRULENCE FACTORS. There is very little known about the virulence factors involved in *M.*

morganii pathogenesis. Despite the paucity of reports, the most significant of these virulence factors are described below, though it should be noted that the data supporting the efficacy of each virulence factor may be minimal or not as substantial as those for the virulence factors of *P. mirabilis*, for example.

Hemolysin. The synthesis of active intracellular hemolysin (Hly) by *M. morganii* follows a pattern similar to that seen with the hemolysins from *E. coli*, *P. mirabilis* and *P. vulgaris*. Emody et al. (1980) measured the virulence of *M. morganii* strains due to hemolysin. Hemolysin (Hly⁺) wild-type strains and Hly⁺ transconjugants were found to be more virulent than Hly⁻ in mice and chick embryos. This enhanced virulence seems to be connected with the production of a diffusible α -hemolysin. There is an important difference between the hemolysins of *M. morganii* and those of *P. mirabilis* and *P. vulgaris*. Koronakis et al. (1987) found that hemolytic activity in all *M. morganii* strains tested was cell free (extracellular), whereas in all *P. mirabilis* and 60% of *P. vulgaris* strains, hemolysin was only found associated with intact cells. The presence of the secretory gene *hlyD* in *M. morganii*, may explain the difference in secretion patterns observed in these two genera.

Urease. While both *P. mirabilis* and *M. morganii* possess urease activity with some similarities, there are also significant differences between the enzymes that may play a role in choice of habitat and pathogenicity. possess ureases, there are distinct differences between the enzymes in the two species that may play a role in habitat and pathogenicity. For example, *M. morganii* urease possesses a higher affinity for urea than *P. mirabilis* urease, but the latter hydrolyzes urea at a rate 6- to 25-fold faster (Jones and Mobley, 1987). *Morganella morganii* survives in acidic conditions and its ureases have been shown to be activated in vitro by low pH, with an unusually low activity optimum of pH 5.5 (Young et al., 1996). In this respect, the urease from *M. morganii* is similar to the urease of *Y. enterocolitica* and *H. pylori*, both of which can hydrolyze urea at significantly higher rates under acidic conditions when compared with other pathogenic bacteria. A critical assessment of whether the *M. morganii* urease is a significant factor in the pathogenesis of this species will ultimately require in vivo studies with urease-negative mutants.

The Genus *Providencia*

Habitat

The members of the genus *Providencia* are all facultative anaerobes and motile by peritrichous flagella (Figs. 2F, G); however, they do not

exhibit cellular differentiation and swarming behavior. Urease production is not characteristic of all *Providencia* species, with only *P. rettgeri* strains producing urease (Brenner et al., 1978).

Providencia stuartii is found most frequently in hospital patients with urinary tract infections. Less frequently, it is found in respiratory and skin infections (Stickler et al., 1985; Warren, 1986). *Providencia alcalifaciens* is generally isolated from stool samples along with other enteric pathogens. A similar species (*P. rustigianii*), was originally isolated from human feces as *P. alcalifaciens* biogroup 3 (Ewing et al., 1972) and subsequently redesignated as a separate species (Hickman-Brenner et al., 1983). It has since been isolated from a range of human and animal sources, including (oddly enough) penguin feces (Costas et al., 1987; Muller, 1983). While this species can colonize the human gastrointestinal tract and some of the sources included diarrheal patients, no direct link with diarrhea has been established.

The third, taxonomically defined species of *Providencia*, *Providencia heimbachae*, was first described by Muller 1986 (Muller et al., 1986b) who isolated it from penguin feces and from an aborted bovine fetus. A strain of this species recently has been isolated from humans, specifically, the stool of a patient with idiopathic diarrhea (Mohr O'Hara et al., 1999). It should be noted, however, that this strain possesses important biochemical and physiological differences compared to the type strain of Muller (Muller et al., 1986b). While the type strain is positive for phenylalanine deaminase, gas production from glucose and fermentation of maltose and D-mannitol, the human isolate is negative for these tests. Furthermore, motility is only observed after 6 days for the human isolate, compared with 4 days for the type strain.

Isolation and Identification

Isolation of *Providencia* sp. is routinely performed using bacteriological nutrient media for the general identification of *Enterobacteriaceae*, and, together with the biochemical tests shown in Table 2, to discriminate this species from other enteric forms. Machtiger et al. (1971) found that *P. stuartii* and *P. alcalifaciens* required five amino acids (isoleucine, leucine, valine, glutamic acid and cystine), as well as niacin, for growth on minimal medium containing glucose as a carbon source (Machtiger and O'Leary, 1971). Hawkey et al. (1982b) used a selective and differential enrichment medium to isolate low numbers of *P. stuartii*. Thaller et al. (1992) used a modified MacConkey containing methyl green phosphatase (MGP) to successfully identify 100% of *P. stuartii* isolates from 1,278 seeded

urine samples. By comparison, standard MacConkey medium and the API20E (API System, Bio Merieux Vitec, Inc. Hazelwood, MO.) were only able to identify 82.5% of the same isolates. *Providencia stuartii* and *M. morganii* are the only phosphatase-positive members of the *Enterobacteriaceae*, and MGP distinguishes phosphatase producing colonies on Luria-Bertani-agar by their green pigmentation or halo (Pompei et al., 1990; Satta et al., 1979), while on MacConkey medium the same colonies appear red. Thaller et al. (1992) also added methyl blue to MCP to distinguish lactose-positive colonies (violet) from the phosphatase producers.

A simplified method for the identification of *P. alcalifaciens* has been described by Senior (1997). This method relies on the probability that *P. alcalifaciens* is the only oxidase-negative organism likely to be present in fecal cultures enriched in tetrathionate broth, which also is unable to ferment the mannitol, xylose and galactose present in the medium. When grown on this agar-solidified medium, colonies of *P. alcalifaciens* appear red, in contrast to the colorless colonies of non-*P. alcalifaciens* bacteria that ferment the three sugars. Extensive tests by Senior showed the medium to be both highly specific and sensitive in detecting *P. alcalifaciens* (Senior, 1997). A number of commercial kits have become available for identification purposes and have been utilized, with varying success, for identification of *P. rustigianii* (Kitch et al., 1994; Piccolomini et al., 1991).

Ecology

The emergence of *P. stuartii* as a significant hospital pathogen since the 1970s has led to efforts to uncover the natural sources and reservoirs of this species. Early work had discounted the gastrointestinal tract as a potential site owing to the lack of isolates obtained using traditional fecal culture methods; however, Hawkey et al. (1982a) demonstrated fecal colonization by *P. stuartii* using a combination of pre-enrichment and selective media. Moreover, the long-term-catheterized human urinary tract appears to offer an attractive niche to this species. Results from studies of patients catheterized for long periods indicate that *P. stuartii* can often be found on catheter surfaces as frequently as more familiar uropathogens such as *E. coli*, *P. mirabilis*, *Enterococcus* sp., and *P. aeruginosa* (Warren, 1986). It also has been isolated from burn and wound infections and bacteremias, which further emphasizes the pathogenicity of this species (Penner, 1984).

Providencia rettgeri similarly has emerged in recent years as a nosocomial pathogen of clinical importance. This species has been isolated with

regularity from the urinary tract of catheterized or immunocompromised patients and less frequently from human feces, bile and sputum (Bauernfeind and Wiersma, 1977; Cipriani et al., 1988; Gunalp, 1979; Mino et al., 1997). Of the remaining species, *P. alcalifaciens* is an intestinal colonizer and a recognized cause of gastroenteritis (Janda et al., 1998). *Providencia rustigianii* also has been confirmed as a gastrointestinal tract inhabitant and often is found in the intestinal tract of mammals, such as humans and pigs, and even in arctic birds, e.g., penguins. The true ecological niche inhabited by *P. heimbachae* has yet to be determined, but the evidence at hand suggests that it may inhabit the gastrointestinal tract, as is common for other *Providencia* species (Costas et al., 1987; Higashitani et al., 1995; Mohr O'Hara et al., 1999).

Epidemiology

Both the indirect hemagglutination test and the indirect hemagglutination inhibition test have been used to type *Providencia* sp (Levina et al., 1980). These tests are frequently useful in distinguishing between individual *Providencia* serogroups (Levina et al., 1980). Antigenic serotyping methods based on the flagellar (H), LPS (O) and capsular (K) antigens also have been applied to *P. stuartii* strains. Such serotyping may be particularly useful in identifying specific strains endemic in different hospitals. Penner and colleagues have used O serotyping successfully (Penner and Hennessy, 1979a; Penner and Hennessy, 1979b; Penner et al., 1979c) to type strains from *P. stuartii*, *P. rettgeri* and *P. alcalifaciens* (Penner and Hennessy, 1979a; Penner and Hennessy, 1979b). In the O serotyping of *P. stuartii* isolates, Penner and his colleagues found that 97% of 829 isolates tested fell into one of 14 O-antigen serotypes. However, the somatic (O) antigen serotyping scheme for 54 isolates of *P. rettgeri* based upon a set of 93 O-antigens, also developed by Penner and Hennessy (1979b), failed to detect a single predominant serotype. While the small size of the strain pool may have influenced this latter result, it is possible that infection by *P. rettgeri* is not due to a few serotypes, as has been found in is much less strain specific than that by *P. stuartii*. Similarly, in the serotyping of *P. alcalifaciens*, Penner (1979c) detected 29 serotypes among 82 typeable isolates. Serotyping schemes for the remaining species of *Providencia* have yet to be developed but will undoubtedly employ similar approaches to those used for other *Providencia* species.

Bacteriophage and bacteriocin typing methods for *Providencia* sp. have yet to be developed, though a number of studies have looked for and isolated bacteriophages from both *P. stuartii* and *P. rettgeri* (Coetzee, 1967; Gabrilovich et al.,

1998; McHale et al., 1981a). A bacteriocin typing scheme has been tested on >300 *Providencia* sp. isolates, though no follow-up confirmation of its reliability has been published (Al-Jumaili and Fenwick, 1978).

Molecular methods of epidemiological typing, such as restriction fragment length polymorphism (RFLP) and ribotyping, have been used with *P. stuartii* and *P. alcalifaciens*. Owen et al. (1988) noted that the DNA restriction fingerprints for *P. stuartii* were quite distinct from species of the allied genera of *Providencia* and *Proteus*, and provided a more sensitive measure of minor genomic differences than total DNA digests. Rahav et al. (1994) used RFLP to demonstrate that a single strain of *P. stuartii* persisted in the same patient during a nursing home outbreak of *P. stuartii* bacteriuria, and that several different strains were responsible for the outbreak. In comparison, neither biochemical tests nor antibiotic sensitivity were able to distinguish separate strains during this outbreak. Guth et al. (1999) used clonal analysis based on ribotyping to show that diarrheal isolates of *P. alcalifaciens* were clustered into two main groups.

The application of genetic methods to the identification of bacteria has become routine in the past decade and this is reflected in the current methods being applied to identification of *Providencia* sp. Apart from classical ribotyping, other methods that potentially could be used to distinguish strains of *Providencia* include automated ribotyping, RAPD-PCR (Akopyanz et al., 1992), amplification and restriction analysis of the 16S rRNA gene (ARDRA; Andrighetto, 1998; Dijkshoorn, 1998) and multilocus sequence typing (MLST), which exploits the electronic portability of nucleotide sequence data (Maiden et al., 1998).

Pathogenicity

The *Providencia* species that have been clearly identified as pathogens are *P. stuartii*, *P. rettgeri* and *P. alcalifaciens*. In human pathogenicity, the most significant member of the genus is *P. stuartii*, whereas the virulence of *P. rettgeri* and *P. alcalifaciens* is less clear. *Providencia stuartii* is particularly effective in colonizing urinary catheters and is a leading risk factor for bacteremia (Muder et al., 1992; Rahav et al., 1994; Rudman et al., 1988; Woods and Watanakunakorn, 1996). It has been proposed that *P. stuartii*, as well as *P. mirabilis* and *M. morganii*, probably establish a niche within the urinary catheter, thus increasing their ability to cause subsequent bladder bacteriuria (Warren, 1987a). *Providencia stuartii* is not particularly invasive; however, certain circumstances tend to increase the probability of infection, including prolonged catheterization and urinary surgery. This species also is resistant

to many common antibiotics, including most penicillins, aminoglycosides, tetracyclines, older cephalosporins, sulfamethoxazole and fosfomycin (Gomez-Lus et al., 1977; Paradise et al., 1998; Rather et al., 1997; Stock and Wiedemann, 1998; Swiatlo and Kocka, 1987). Such antibiotic resistance gives *P. stuartii* an opportunistic advantage in nosocomial patients. Furthermore, *P. stuartii* also has been implicated in septicemia (bacteremia), with symptoms typical of other septicemias, except that vascular collapse is not a prominent feature (McHale et al., 1981b; Prentice and Robinson, 1979).

While cases of *P. stuartii* septicemia usually prove fatal due to antibiotic resistance, patient survival in response to medical therapy has been reported in individual case studies (Keren and Tyrrel, 1987) and more recently, in long-term epidemiological surveys (Muder et al., 1992; Woods and Watanakunakorn, 1996). In the latter case, Woods and Watanakunakorn (1996) found a mortality rate of 25% in a review of 49 cases of *P. stuartii* bacteremia. Considering that 51% of patients in this survey were infected by more than one bacterial species (polymicrobial bacteremia), the mortality rate for *P. stuartii* bacteremia alone is probably lower. The main differences between *P. stuartii* and *P. rettgeri* are at the biochemical level. *Providencia rettgeri* can metabolize the sugars D-arabitol, adonitol and erythritol (Table 2). Otherwise, most *P. rettgeri* strains exhibit pathogenic properties similar to those of *P. stuartii*. *Providencia rettgeri* UTIs in catheterized and otherwise compromised patients are also difficult to treat owing to multiple antibiotic resistance. Overall resistance is, however, less marked in this species than in *P. stuartii*. By way of example, *P. rettgeri* is particularly susceptible to the aminoglycosides gentamicin and tobramycin, whereas *P. stuartii* is highly resistant to both (Penner and Preston, 1980b; Penner et al., 1982; Piccolomini et al., 1987).

In contrast to *P. stuartii* and *P. rettgeri*, *P. alcalifaciens* is an invasive enteric pathogen and implicated as a cause of diarrheal disease (Albert et al., 1992; Albert et al., 1998; Guth and Perrella, 1996; Haynes and Hawkey, 1989; Sen, 1962). In studies using pure cultures derived from stool specimens that were inoculated into the ilea of adult rabbits with removable ileal ties (RITARD model; Davis, 1991; Spira, 1981), it has been shown that the development of diarrhea is accompanied by an intestinal histopathology typical of other invasive bacterial species, such as *Shigella flexneri* (Albert et al., 1992). Mathan et al. (1993) have added more evidence to the *P. alcalifaciens* virulence model, invasiveness model by demonstrating two modes of bacterial entry into epithelial cells. The first mode of entry is by direct endocytosis associated with polymerization of cytoskeletal components, and the sec-

ond mode by which the bacteria enter is through disruption of tight junctions, with the bacteria entering into and proliferating in intercellular spaces. The invasive abilities of *P. alcalifaciens* have been tested in HEp-2 cells (an epithelioid cell line from a human laryngeal carcinoma) by two independent scientific groups (Albert et al., 1992; Janda et al., 1998). Both groups were able to confirm penetration by *P. alcalifaciens* isolates, whereas no strain of *P. stuartii* or *P. rettgeri* tested invaded the HEp-2 cells.

VIRULENCE FACTORS. Those contributing to the pathogenicity of *Providencia* sp. that have been investigated include cellular adherence, the production of fimbriae and of urease. *Providencia stuartii* has been the focus of the majority of research.

Adherence and fimbriae. Urinary tract infections (UTIs) due to *P. stuartii* persist longer than those due to other Gram-negative bacteria. It has been suggested that a possible reason for this increased persistence may be due to the ability of *P. stuartii* to adhere to uroepithelial cells (Mobley et al., 1986). Adherence to uroepithelial cells can be enhanced by the expression of MR/K (hemagglutinin)-type fimbriae (see "Fimbriae"). Mobley et al. (1988) found that a significant proportion of *P. stuartii* isolated from patients experiencing bacteriuria of long duration expressed MR/K fimbriae. These data implicate the MR/K hemagglutinin in an important role in UTI persistence of *P. stuartii*.

Urease. While *Providencia rettgeri* is urease positive, as are some strains of *P. stuartii*. In fact, *P. rettgeri* and *P. stuartii* were originally subdivided based on urease production (Penner et al., 1976). There is some evidence that urease-producing strains of *P. stuartii* are more likely to be involved in long-term colonization of urinary catheters with subsequent development of blockages due to stone formation (Kunin, 1989; Stickler et al., 1998). Urease-producing *P. stuartii* strains also have been found to inhibit the in vitro growth of *E. coli* on catheter surfaces and in urine (Fletcher et al., 1994). This adaptive advantage in growth may explain why *P. stuartii* are the dominant species isolated in these mixed infections. The construction of isogenic urease-negative mutants may help to better define the role of urease in *P. stuartii* pathogenesis.

Conclusion

The genera *Proteus*, *Morganella* and *Providencia* contain a number of important human pathogens that often cause serious infections in hospitalized and immunocompromised patients. Other species are normal intestinal flora in animals or animal pathogens. One of the most conspicuous features of members of the genus *Proteus* is their

ability to differentiate into elongated, multinucleated swarmer cells upon contact with a solid surface. Methods of isolation and identification have been developed for most species and these now include several DNA-based methods of detection; however, treatment of infected patients is often problematic owing to the development of antibiotic resistance and the immunocompromised state of the patient.

The information contained in this chapter gives the reader a broad understanding of the current state of knowledge concerning these related genera. There are a number of areas where this knowledge base needs strengthening in the future. For example, our understanding of the ecological and/or pathogenic role of several species, including *P. myxofaciens*, *P. rustigianii* and *P. heimbachae*, has advanced very little since their initial identification, and much work remains to be done in this regard.

Acknowledgments. This work was supported by grants from the National Institutes of Health (DK49720) and the National Science Foundation (MCB9514803). We wish to express our appreciation to Rachel Schneider, of the Center of Marine Biotechnology, University of Maryland Biotechnology Institute, for the sequencing of the 16S rRNA sequences of the tribe *Proteeae* (Fig. 1), and Dr. Robert K. Naumann of the Electron Microscopy Unit, Dental School, University of Maryland, Baltimore, for the electron micrographs of selected *Proteeae* (Fig. 2).

Enteropathogenic *Yersinia*: Introduction (Elisabeth Carniel)

The genus *Yersinia* belongs to the family Enterobacteriaceae and is currently composed of 11 species. Three of them are pathogenic for humans and animals: the enteropathogens *Y. pseudotuberculosis* and *Y. enterocolitica* and the plague agent *Y. pestis*. This chapter deals with the two enteropathogenic species, while *Y. pestis* is described in the *Yersinia Pestis* and Bubonic Plague in this Volume.

Taxonomy

Van Loghem in 1944 (Van Loghem, 1944) proposed the separation of the genus *Yersinia* from the genus *Pasteurella*, which became effective in 1974 (Mollaret and Thal, 1974).

Yersinia pseudotuberculosis was first described by Malassez and Vignal in 1883 (Malassez and Vignal, 1883; Malassez and Vignal, 1884). This bacterium received numerous names (Mollaret, 1965): bacille de la tuberculose zoogléique, *Bacillus pseudotuberculosis*, *Bacterium pseudotuberculosis rodentium*, *Pasteurella pseudotuberculosis*, before being finally designated *Y. pseudotuberculosis* in 1974 (Mollaret and Thal, 1974).

Yersinia enterocolitica was first described in 1939 by Schleifstein and Coleman (Schleifstein et al., 1939) who called it *Bacterium enterocoliticum* in 1943 (Schleifstein and Coleman, 1943). Different names were subsequently given to this organism: *Pasteurella pseudotuberculosis*-like, *Pasteurella pseudotuberculosis* type B, *Pasteurella* X, *Pasteurella* Y, Germe X, and finally *Y. enterocolitica* in 1964 (Frederiksen, 1964). It appeared later on that this species was heterogeneous and contained several related species designated “*Y. enterocolitica*-like” (Brenner et al., 1980b). Taxonomical studies allowed the separation of *Y. enterocolitica* sensu stricto (Bercovier et al., 1980a) from *Y. enterocolitica*-like species: *Y. intermedia* (Brenner et al., 1980a), *Y. kristensenii* (Bercovier et al., 1980b), *Y. fredericksonii*

(Ursing et al., 1980), *Y. aldovae* (Bercovier et al., 1984) and *Y. rohdei* (Aleksic et al., 1987). These widespread environmental species are usually not associated with disease. More recently, *Y. mollaretii* and *Y. bercovieri* were also separated from *Y. enterocolitica* (Wauters et al., 1988b). These two species formerly belonged to biogroups 3A and 3B of *Y. enterocolitica*, respectively. Their importance in pathogenesis is for the moment unknown, but they seem to be devoid of virulence-linked properties. *Yersinia ruckeri* (Ewing et al., 1978; De Grandis et al., 1988b) is an important fish pathogen responsible for the red mouth disease in rainbow trout and some other fish. However, its classification in the genus *Yersinia* is controversial.

Like other members of the family Enterobacteriaceae, *Y. enterocolitica* and *Y. pseudotuberculosis* are Gram-negative, aero-anaerobic rods. They still have some particularities that distinguish them from the other members of this family. They are motile at temperatures inferior to 30°C only, they form colonies in 48 h instead of 24 h, their optimal growth temperature is around 30°C, they are able to multiply at low temperatures (4°C), and they have a G+C content (46–49 mol%) lower than that of most members of this family.

History

DNA/DNA hybridization studies performed in the 1980s demonstrated that *Y. enterocolitica* is the most distantly related pathogenic species of *Yersinia* (Bercovier et al., 1980a). *Yersinia pestis* and *Y. pseudotuberculosis* exhibit such a high degree of DNA relatedness that they should have been included into a single species (Bercovier et al., 1980b). However, *Y. pestis* causes plague and is transmitted by fleabites, whereas *Y. pseudotuberculosis* is transmitted by the fecal-oral route and rarely leads to death. Because of the historical importance of *Y. pestis* in human history and for the sake of security, the reclassification of *Y. pestis* and *Y. pseudotuberculosis* into a single species has been rejected.

A more recent analysis of the three pathogenic species by multilocus sequence typing (MLST) indicated that the separation between *Y. pestis*/*Y. pseudotuberculosis* and *Y. enterocolitica* occurred 42–187 million years ago, and that the last common ancestor of *Y. pestis*/*Y. pseudotuberculosis* existed 0.4–1.9 million years ago (Achtman et al., 1999). *Yersinia pestis* was found to be a clone that evolved from *Y. pseudotuberculosis* 1500–20,000 years ago, shortly before the first known pandemics of human plague. Despite their long existence, the enteropathogenic species *Y. enterocolitica* and *Y. pseudotuberculosis* were not known before the end of the nineteenth century.

Yersinia enterocolitica, first described in the United States in 1939, was subsequently isolated in Europe some ten years later. Before 1966, the organism was isolated from a wide variety of animal species, but no more than 23 cases of human infection were reported in the literature worldwide. However, this number dramatically increased over the next years and *Y. enterocolitica* is now found all over the world, with a higher incidence in temperate and cold countries. The first major foodborne human outbreak of this organism was reported in the United States in 1976, but *Y. enterocolitica* is most often responsible for sporadic cases.

Yersinia pseudotuberculosis was identified in 1883, before *Y. enterocolitica*. This species infects a wider range of animals than *Y. enterocolitica* but its importance in human infections is much lower than that of *Y. enterocolitica* worldwide.

Both species are transmitted by the oral route and cause intestinal symptoms such as abdominal pain (especially *Y. pseudotuberculosis*), diarrhea (especially *Y. enterocolitica*), and fever.

The epidemiology, clinical features, immunology, virulence factors, physiopathology, bacterial diagnosis, and treatment of these two species will be described in the various paragraphs of this chapter.

Yersinia enterocolitica

Epidemiology (Elisabeth Carniel)

That *Yersinia enterocolitica* is a global pathogen has been suggested by numerous reports, which are summarized in different reviews (Mollaret, 1976; Swaminathan et al., 1982; Cover and Aber, 1989; Bottone, 1997; Bottone, 1999; Naktin and Beavis, 1999).

GEOGRAPHICAL DISTRIBUTION *Yersinia enterocolitica* has been isolated in various countries on all five continents.

Several countries in Asia: Bangladesh (Butler et al., 1984; Carniel et al., 1986), China (Seto and

Lau, 1984; Ding et al., 1986; Zheng and Xie, 1996; Fukushima et al., 2001a), India (Abraham et al., 1997), Iran (Haghighi, 1979), Israel (Shmilovitz and Kretzer, 1978), Japan (Kanazawa and Ikemura, 1979; Kato et al., 1985; Saitoh et al., 1994; Hosaka et al., 1997), and Turkey (Gonul and Karapinar, 1991).

All European countries including Belgium (Wauters, 1972; Wauters, 1979; Mollaret et al., 1979; Vandepitte and Wauters, 1979; Wauters and Vandepitte, 1982; Verhaegen et al., 1998), Finland (Hamama et al., 1992), Czechoslovakia (Rakovsky et al., 1973), France (Alonso et al., 1979; Mollaret et al., 1979; Servan et al., 1979; Mollaret and Alonso, 1988), Germany (Nesbakken, 1988), Hungary (Szita and Svidro, 1976), Norway (Kapperud, 1981; Saebo and Lassen, 1992; Kapperud and Vardund, 1995), Russia (Iushchenko et al., 1982; Sharapova and Alekseeva, 1983; Gurleva et al., 1985; Pavlov, 1985), and Sweden (Hurvell et al., 1979).

South and North America: Argentina (De Centorbi et al., 1989; Escudero et al., 1991), Brazil (Pizzolitto et al., 1979), Canada (Lafleur et al., 1972; Lafleur et al., 1979; Toma, 1973; Toma and Lafleur, 1974; Toma et al., 1979; Schiemann and Fleming, 1981b; Hariharan et al., 1995; Letellier et al., 1999), and the United States (Eden et al., 1977; Bottone and Robin, 1979; Shayegani et al., 1979; Marymont et al., 1982; Walker and Grimes, 1985; Naqvi et al., 1993).

A few places in Africa: Morocco (Hamama et al., 1992), South Africa (Jennings et al., 1987), and West Africa (Anjorin et al., 1979).

And in Oceania: New Zealand, Australia (Saitoh et al., 1994).

The incidence of yersiniosis is higher in temperate and cold countries. *Yersinia enterocolitica* was found to be the causative agent of 2.8% of the enteritis in Montreal (Marks et al., 1980), 2.9% in the Netherlands (Hoogkamp-Korstanje et al., 1986), and 1.4% in Italy (Mingrone et al., 1987). In Norway, this species was the fourth leading cause of acute enteritis (1%) after *Salmonella* (5%), *Campylobacter* (3%) and *Shigella* (3%). In Belgium, *Y. enterocolitica* was found to be the third most common bacterial enteropathogen after *Salmonella* and *Campylobacter* (Verhaegen et al., 1991). In New York State, *Y. enterocolitica* was isolated from 10 to 25% of 275 water, milk, and animal specimens examined and from about 2.3% of 300 sequential stool specimens submitted for *Salmonella* and *Shigella* screening (Shayegani et al., 1979).

Bioserotype 4/O:3 strains are the most common pathogenic *Yersinia enterocolitica* found over the world (Mollaret et al., 1979; Marriott, 1987; Mingrone et al., 1987), followed by 2/O:9 strains. The phage type of 4/O:3 strains differentiates them into three main subgroups: phage type

VIII, which is widespread in Europe and in many other countries; phage type IXa, which is found essentially in South Africa and Hungary; and phage type IXb, which is restricted to Australia, New Zealand, the United States, and Canada (Nicolle et al., 1976; Pham et al., 1995; Bottone, 1997).

Bioserotype 2/O:9 strains are the major cause of *Y. enterocolitica* diarrhea in the United Kingdom (Prentice et al., 1991).

Yersinia enterocolitica 1B/O:8 were restricted to North America and were the predominant bioserotype in the United States in the past few decades (Kay et al., 1983); however, these strains are now isolated in other parts of the world and their importance decreased in the United States in the mid- to late 1980s (Bottone et al., 1987; Bissett et al., 1990). The major bioserotype found in this country is now 4/O:3.

RESERVOIRS A wide variety of ecological niches may shelter *Y. enterocolitica*.

The environment (soil and water; Wauters, 1972; Kapperud, 1977; Botzler, 1979; Botzler, 1987; Iushchenko, 1982; Walker, 1985; Ziegert, 1990; Gonul, 1991; Saitoh, 1994)

Food (milk, retail meat products, vegetables, eggs, cheese, etc.; Iushchenko et al., 1982; Pavlov, 1985; Ding et al., 1986; Schiemann, 1987; De Centorbi et al., 1989; Hamama et al., 1992; Durisin et al., 1997)

A wide range of animals: domestic (cat and dog), stock farm (chinchilla, mink, pig, rabbit, cow, goose, horse, sheep, and buffalo), zoo (monkey), wild (raccoon, fox, snail, frog, beaver, deer, ocelot, crab, flies, and fleas), birds (robin), shellfish (oyster), and many species of small rodents (McClure et al., 1971; Wauters et al., 1971; Alonso and Bercovier, 1975; Toma and Deidrick, 1975; Wauters and Janssens, 1976; Kapperud, 1977; Servan et al., 1979; Iushchenko et al., 1982; Gurleva et al., 1985; Kato et al., 1985; Walker and Grimes, 1985; Shayegani et al., 1986; Weber et al., 1987; Cox et al., 1990; Escudero et al., 1991; Weynants et al., 1996; Zheng and Xie, 1996; Funk et al., 1998; Letellier et al., 1999; Naktin and Beavis, 1999)

Most of the strains isolated from the environment belong to the nonpathogenic biotype 1A, with the exception of pathogenic strains of biotype 1B, which are frequently isolated from water.

Pathogenic *Y. enterocolitica* of biotypes 2 to 5 are mainly isolated from animals (sheep, cattle, goats, and poultry) or food. There is a preferential relationship between the bioserotype of the strains and their ecological niches (Mollaret, 1976; Bottone, 1997): 4/O:3 strains are isolated with a high frequency from pigs; 2/O:9 strains are often found in cows and goats; the reservoir of

strains of bioserotypes 2 or 3/O:5,27 (the third most common *Y. enterocolitica* pathogen in Europe after 4/O:3 and 2/O:9 strains) is not clearly established; strains of the very rare bioserotypes 5/O:2,3 are isolated from sheep, hares and goats (Slee and Button, 1990), and 3/O:1,2a,3 from chinchillas (Bercovier et al., 1980a).

TRANSMISSION Transmission of *Y. enterocolitica* occurs by the fecal-oral route. The organisms are ingested with contaminated food. After their journey in the intestinal tract of their host (where they exert their pathogenic effect; Physiopathology of *Y. enterocolitica* and to Clinical symptoms of *Y. enterocolitica*), they are excreted in the feces, which can serve as a source of contamination of a new host or of the environment.

Children below the age of five are much more prone to *Y. enterocolitica* infections (Mollaret, 1976; Cover and Aber, 1989) because they have weaker defense mechanisms, immature bacterial flora in their intestines, behaviors favoring bacterial infections (crawling and suckling), and surveillance of diarrhea is more intensive in infants than in adults.

Peaks of human yersinioses have been reported to predominate during the cold season (Mollaret, 1976; Swaminathan et al., 1982); however, this does not appear to be the case over the last years in France where the majority of the strains (including pathogenic ones) are predominantly isolated during the summer (French National Reference Laboratory, unpublished data).

Sporadic Human Cases Yersinia enterocolitica 4/O:3 and 2/O:9 most often cause isolated cases or small family outbreaks, although they have been implicated in a few community outbreaks.

One of the major sources of human infection with pathogenic *Y. enterocolitica* 4/O:3 is through the handling of swine and the consumption of pork meat (Tauxe et al., 1987). Pigs are known to carry the organism in their oropharynx, nasopharynx, and their intestine. Contamination by *Y. enterocolitica* of pigs and of pig carcasses in slaughterhouses has been largely documented (Toma and Deidrick, 1975; Wauters and Janssens, 1976; Nicol, 1978; Asakawa et al., 1979; Hurvell et al., 1979; Doyle et al., 1981; Schiemann and Fleming, 1981b; Harmon et al., 1984; Walker and Grimes, 1985; Andersen, 1988; Nesbakken, 1988; De Boer et al., 1991; Trallero et al., 1992; Hariharan et al., 1995; Letellier et al., 1999; Naktin and Beavis, 1999). For instance, in one study (Andersen, 1988), 24.7% of 360 freshly slaughtered pig carcasses were found infected with *Y. enterocolitica* 4/O:3. The source of contamination was the intestinal content of the pigs.

The use of a mechanized bung cutter in connection with enclosing the anus and rectum in a plastic bag to minimize fecal contamination was recommended to reduce infection of pork meat. In Norway, up to 83% of slaughtered pigs were carriers of high numbers of *Y. enterocolitica* 4/O:3 on their tongue and tonsils (Nesbakken, 1988). Consumption of raw or undercooked infected meat may then cause human infections (Tauxe et al., 1987; Stoddard et al., 1994; Kellogg et al., 1995). The infected meat may also serve as a source of contamination of other food products by direct contact with these products or via infected knives, hands, or recipients.

Cows, goats and sheep may also be a source of human infection with *Y. enterocolitica*, but the bioserotype of these isolates is most often 2/O:9. This represents a major problem for stock farmers because antibodies against serotype O:9 crossreact with *Brucella* antigen (Weynants et al., 1996; Gerbier et al., 1997; Garin-Bastuji et al., 1999), and suspicion of brucellosis should lead to the elimination of the animals according to public health regulations. It is not yet clear whether human infections with *Y. enterocolitica* 2/O:9 occur directly by handling the animals or by eating their contaminated meat, or indirectly by the consumption of vegetables infected by the animal feces.

Infected greenery may thus be a primary source of human infection. The ability of *Yersinia* strains to multiply at 4°C is an important factor to take into consideration. Storage of food in refrigerators was probably one of the major reasons for the sudden "explosion" of yersiniosis cases in the 1950s. Foodstuffs infected with a low number of pathogenic *Y. enterocolitica* may not cause any symptom if consumed immediately, while the same product kept in the refrigerator will be heavily loaded with *Yersinia* after a few days, and may then cause a disease. The inoculum of *Y. enterocolitica* required to cause intestinal symptoms has been determined to be 10⁹ bacteria/ml (Edelman and Levine, 1980).

Person-to-person transmission, although scarcely documented, probably represents another mode of circulation of pathogenic *Y. enterocolitica* through infected hands. Family outbreaks may be due to consumption of a common infected meal but the sequential onset of illness in family members also suggests a possible person-to-person transmission (Ahvonen, 1972; Gutman et al., 1973; Fukushima et al., 1981; Martin et al., 1982). Excretion of *Y. enterocolitica* in the stools of children with enteritis may last 14–97 days (Marks et al., 1980). A few cases of nosocomial infections have been reported (Toivanen et al., 1973; Ratnam et al., 1982; McIntyre and Nnochiri, 1986). However, the isolation of nonpathogenic strains of biotype 1A in two of these three out-

breaks suggests that these isolates were probably not the cause of the symptoms.

Strains of bioserotype 1B/O:8 may also be, although seldom are, responsible for sporadic cases of human infections following ingestion of contaminated water (Keet, 1974).

LARGE COMMUNITY OUTBREAKS Large human outbreaks due to *Y. enterocolitica* are most often associated with strains of bioserotype 1B/O:8 and have been reported only in the United States (Bottone, 1997). The first major human foodborne outbreak of *Y. enterocolitica* O:8 infection occurred in New York State in 1976, among children and employees of several schools who had consumed chocolate milk contaminated with this bacterium (Black et al., 1978). Another outbreak due to absorption of powdered milk was reported in 1981 in a summer camp in New York (Shayegani et al., 1983). The same year, the consumption of tofu washed with contaminated water resulted in an outbreak caused by *Y. enterocolitica* O:8 in Washington (Tacket et al., 1985). Contaminated water used to wash bean sprouts was also responsible for a *Y. enterocolitica* O:8 outbreak in a Brownie troop in Pennsylvania in 1982. Recently another outbreak due to *Y. enterocolitica* 1B/O:8 occurred in Vermont and New Hampshire and was associated with consumption of bottled pasteurized milk from a local dairy (Ackers et al., 2000). This outbreak likely resulted from post-pasteurization contamination of milk.

However, other bioserotypes of *Y. enterocolitica* have been associated in some rare instances with human outbreaks. This was the case among people who participated in a feast in Tamil Nadu village (India) where buttermilk contaminated with a 4/O:3 strain was consumed (Abraham et al., 1997). An outbreak associated with the household preparation of chitterlings contaminated with a strain of the same bioserotype was also reported in Georgia in 1989 (Lee et al., 1990). Finally, contamination of pasteurized milk with a *Y. enterocolitica* isolate of serotype O:13a,13b caused a large outbreak in three states in the United States in 1982 (Tacket et al., 1985).

A few other foodborne outbreaks have been suspected to be due to *Y. enterocolitica*, although the role of this species as the causal agent could not be confirmed. Infected water has been reported to be the source of a *Y. enterocolitica* outbreak involving 41% of the visitors and employees who were at a ski resort in Montana (Eden et al., 1977).

MOLECULAR EPIDEMIOLOGY *Yersinia enterocolitica* strain differentiation has relied, until recently, on phenotypic characteristics (biotype, serotype, and phage type). Since these markers exhibit a

very low degree of polymorphism, the establishment of an epidemiological link between two strains based on their sharing the same bioserotype is not fully satisfactory. Recent advances in enzymatic (multi-locus enzyme electrophoresis [MLEE]) and genetic (restriction endonuclease analysis of the plasmid [REAP], ribotyping, restriction enzyme digestion of the chromosome [REAC], polymerase chain reaction [PCR]-fingerprinting, and pulsed-field gel electrophoresis [PFGE]) techniques have provided a means to reevaluate the polymorphism of isolates within a given bioserotype, and therefore to trace the spread of some clones over the world or during a local outbreak.

Multi-locus Enzyme Electrophoresis Analyses of the electrophoretic metabolic enzyme polymorphism of *Yersinia* spp. have shown that *Y. enterocolitica* strains belong to one cluster and that subgroups within this cluster most often match the bioserotypes of the isolates (Goullet and Picard, 1984; Goullet and Picard, 1988; Dolina and Peduzzi, 1993). However, within one bioserotype of *Y. enterocolitica*, the discriminatory power of MLEE was not satisfactory because strains of the same serotype were also of the same electrophoretic type (ET) and strains of different serotypes could be of the same ET and thus could not be distinguished.

Restriction Endonuclease Analysis of the Plasmid In this technique, the pYV virulence plasmids present in all pathogenic *Yersinia* (pYV) are extracted, digested with a restriction enzyme, and their banding patterns are compared. This method has the advantage of being rapid and easy to perform, but it is not applicable to nonvirulent *Yersinia* or to virulent strains spontaneously cured of their pYV (easily observed upon subculture or growth at 37°C).

Several studies have reported the use of REAP to compare *Y. enterocolitica* strains (Heesemann et al., 1983; Wachsmuth et al., 1984; Kaneko and Maruyama, 1987a; Kaneko and Maruyama, 1987b; Kapperud and Nesbakken, 1987a; Nesbakken et al., 1987; Kapperud et al., 1990; Kapperud et al., 1991; Fukushima et al., 1993; Fukushima et al., 1998a; Iteman et al., 1996). All studies used the restriction enzymes *EcoRI* and *BamHI* to digest plasmid DNA (and *HindIII* in addition in two studies; Kaneko and Maruyama, 1987a; Kaneko and Maruyama, 1987b). In almost all cases, the plasmid restriction profiles were bioserotype specific, i.e., the REAP pattern was a marker of the bioserotype of the strains. The only exceptions were bioserotypes 2/O:5 and 3/O:3 strains on the one hand (Iteman et al., 1996) and bioserotypes 4/O:3 and 3/O:3 strains on the other hand (Fukushima et al.,

1993), which were found to have identical REAP patterns.

Bioserotype 1B/O:8 strains displayed the highest degree of REAP polymorphism since up to six plasmid restriction profiles could be identified in this group (Kapperud and Nesbakken, 1987a; Nesbakken et al., 1987; Kapperud et al., 1990). Strains of serotype O:5,27 (biotypes 2 or 3) exhibited a moderate degree of polymorphism and could be divided into one to three REAP groups (Kapperud and Nesbakken, 1987a; Nesbakken et al., 1987; Kapperud et al., 1990; Fukushima et al., 1993; Iteman et al., 1996). Strains of bioserotypes 4/O:3 and 2/O:9 displayed the lower degree of REAP diversity. A single plasmid profile was usually observed among 4/O:3 strains (Heesemann et al., 1983; Kaneko and Maruyama, 1987a; Kaneko and Maruyama, 1987b; Kapperud and Nesbakken, 1987a; Nesbakken et al., 1987; Fukushima et al., 1993; Iteman et al., 1996), although two additional plasmid profiles could be identified (in a total of three strains) in one instance (Kapperud et al., 1990). All 2/O:9 strains of worldwide origin studied were highly monomorphic (Heesemann et al., 1983; Kapperud and Nesbakken, 1987a; Nesbakken et al., 1987; Kapperud et al., 1990). Only in two studies could two profiles be distinguished in these strains (Iteman et al., 1996; Fukushima et al., 1998a).

It appears that the plasmid profiles reflect quite well *Y. enterocolitica* bioserotypes but that the degree of polymorphism obtained within a given bioserotype is low. The use of REAP for epidemiological tracing of bacteria during an outbreak might thus not bring valuable information.

PCR-fingerprinting Methods Randomly amplified polymorphic DNA (RAPD) is based on the random amplification of genomic DNA at low annealing temperatures with arbitrarily selected primers. Application of this technique to various *Y. enterocolitica* isolates showed a relatively weak correlation between their RAPD clusters and bioserotypes, and the technique was not sensitive enough to efficiently separate strains within each bioserotype (Rasmussen et al., 1994; Odinet et al., 1995; Leal et al., 1999).

Degenerate oligonucleotide-primed PCR (DOP-PCR), a more recent PCR method that involves multiple locus priming with evenly dispersed sites within a given genome, was also applied to *Y. enterocolitica* isolates (Sayada et al., 1994). However, the number of strains (eight) studied was too low to draw any conclusion about the usefulness of this technique for molecular epidemiology.

Inter-repeat-PCR (IR-PCR) amplifies specific genomic regions known to be variable among

different prokaryotic genomes. The discriminatory power of this technique, involving amplification of enterobacterial repetitive intergenic sequences, was very poor when applied to *Y. enterocolitica* (Odinot et al., 1995).

Ribotyping The ribotyping method is based on the analysis of the restriction fragment length polymorphism generated after hybridization of digested bacterial genomic DNA with an RNA or a DNA 16 + 23 S rRNA probe. This technique was applied to *Y. enterocolitica* by several laboratories, but inter-study comparisons are difficult because of the use of different restriction enzymes: *NciI* and *AvaI* (Andersen and Saunders, 1990), *EcoRI* and *HindIII* (Picard-Pasquier et al., 1990), *NciI* alone (Blumberg et al., 1991), *HindIII*, *NciI*, *BglI*, *SallI*, and *EcoRI* (Mendoza et al., 1996), *EcoRI* and *EcoRV* (Iteman et al., 1996; Fukushima et al., 1998a), and *HindIII* and *BglI* (Lobato et al., 1998). Nonetheless, all studies demonstrated that ribotyping allows to some extent the distinction of subgroups within a given bioserotype, and that the different ribotypes observed are usually bioserotype-specific (i.e., there is a good correlation between phenotypic and ribotypic traits). However, ribotypic polymorphism appears to be higher for strains found in the environment (nonpathogenic strains of biotype 1A or pathogenic strains of biotype 1B) than for those adapted to animal hosts (4/O:3 and 2/O:9).

In a few instances, ribotyping was used to revisit the epidemiological link between strains isolated from a reservoir or a source of infection during an outbreak and those isolated from patients. In one study, no difference in the ribotypes of strains from pigs and human patients could be detected (Andersen and Saunders, 1990), consistent with the hypothesis that pigs are a major reservoir of human yersiniosis. Similarly, the finding of identical ribotype patterns in chitterlings and human specimens from the Atlanta outbreak (Lee et al., 1990) lent further support to the epidemiological evidence that swine were the source of infection and a major reservoir for *Y. enterocolitica* O:3 (Blumberg et al., 1991). However, the fact that only two ribotypes were predominantly found among O:3 United States isolates, and that the ribotypes strictly matched the phage types, indicated that ribotyping did not provide new information compared to classical phenotyping methods in that case. Nonetheless, combination of the patterns obtained with five different restriction enzymes allowed the differentiation of O:3 *Y. enterocolitica* strains from Asturias (Spain) into 11 ribotypes (Mendoza et al., 1996), and the use of only two restriction enzymes (*HindIII* and *BglI*) was sufficient to distinguish nine subgroups. The

two major groups that were found to be endemic in Spain were isolated both from human patients and from commercial raw meat products.

Ribotyping may add some degree of polymorphism to the classical phenotypic markers. However, the limited heterogeneity of the patterns within the most frequent pathogenic bioserotypes suggests that this technique could be useful to trace the spread of *Y. enterocolitica* clones over the world but that it is of more limited interest for outbreak investigations.

PULSED-FIELD GEL ELECTROPHORESIS Attempts were originally made to compare the fragment patterns from the total restriction enzyme digestion of chromosomal DNA (REAC) using classical restriction enzymes and electrophoresis systems (Kapperud et al., 1990; Blumberg et al., 1991). However, the complexity of the patterns made interpretation and comparison of the results extremely difficult.

The use of rare cutting restriction enzymes, which yield a moderate number of DNA fragments, in combination with pulsed-field gel electrophoresis, which separates large-size DNA fragments, allows for analyzing and comparing restriction patterns of whole bacterial genomes.

Application of this technique to *Y. enterocolitica* demonstrated that it is by far the most discriminatory method (Buchrieser et al., 1994; Najdenski et al., 1994; Saken, 1994; Iteman, 1996; Asplund, 1998; Fredriksson-Ahomaa, 1999). The restriction enzymes most frequently used for *Y. enterocolitica* were *NotI* and/or *XbaI*. Digestion with *ApaI* and *XhoI* proved also useful in further subdividing strains within a given *NotI* pulsotype (Fredriksson-Ahomaa et al., 1999). All studies demonstrated that strains are genomically related within each bioserotype, and therefore major serotype-specific pulsotypes can be delineated. Furthermore, within each major pulsotype, *Y. enterocolitica* could be separated into numerous subtypes. In countries such as Finland or Denmark where bioserotype 4/O:3 represents up to 90% of all isolated *Y. enterocolitica*, the availability of a technique that allows the differentiation of this group into various subtypes might prove useful during epidemiological investigations; however, most studies show that one or two pulsotypes usually prevail within a geographical area.

Until now, PFGE has been seldom applied to study links between strains in an epidemiological context. The comparison of the pulsotypes of five pairs of strains isolated either from the same patient at different time intervals, or from siblings, demonstrated that in four cases, the two strains of the same pair displayed identical pulsotypes (Najdenski et al., 1994). In the fifth pair, a single restriction fragment differed between

the two strains, suggesting that genomic polymorphism may be generated rapidly under natural conditions in *Y. enterocolitica*.

Comparison of PFGE with other molecular typing methods such as REAP and ribotyping (Iteman et al., 1996) or MLEE (Saken et al., 1994) on the same *Y. enterocolitica* isolates indicated that in all cases, PFGE patterns were the most polymorphic.

Clinical Manifestations of *Y. enterocolitica* Infections (Mikael Prentice)

GASTROINTESTINAL ILLNESS Most infections are in children under 5 years of age (Prentice et al., 1991; Abdel-Haq et al., 2000) presenting with diarrhea, low-grade fever, abdominal pain and vomiting (Marks et al., 1980; Lee et al., 1990). The diarrhea is persistent (14 days; Marks et al., 1980) and in 25–50% of cases contains frank blood (Tacket et al., 1985; Abdel-Haq et al., 2000). Prospective studies show horizontal spread within families (Marks et al., 1980) and horizontal spread can result in nosocomial disease (Cannon and Linnemann, 1992; Epidemiology of *Y. enterocolitica*). Pharyngitis is often reported, particularly in adults (Cover and Aber, 1989), and *Y. enterocolitica* can be grown from throat swabs in some infected patients (Tacket et al., 1983; Rose et al., 1987). Central abdominal and right iliac fossa pain that may simulate appendicitis (pseudoappendicitis) is more common in older children and young adults (Black et al., 1978; Attwood et al., 1987; Cover and Aber, 1989; Prentice et al., 1991). Although these symptoms have been associated with *Y. enterocolitica* infection for over 30 years (Winblad et al., 1966), it is still very difficult (Shorter et al., 1998) for surgeons to distinguish sporadic appendicitis requiring surgery from pseudoappendicitis due to *Y. enterocolitica* infection (for which surgery is not indicated because it usually resolves spontaneously or with antibiotic therapy; Cover and Aber, 1989). At laparotomy, the usual findings are terminal ileitis with enlarged mesenteric nodes with a slightly edematous or inflamed appendix (Winblad et al., 1966; Cover and Aber, 1989; Shorter et al., 1998). *Yersinia enterocolitica* can be grown from the mesenteric nodes and the appendix (Winblad et al., 1966; Verhaegen et al., 1998).

Histology in the severe cases coming to post-mortem shows ulceration and necrosis of the bowel overlying lymphoid follicles extending over the length of the gastrointestinal tract from small intestine (in some cases stomach) to colon (Bradford et al., 1974; Physiopathology). Mesenteric lymph nodes are enlarged showing focal areas of necrosis (Bradford et al., 1974) and infiltration by leucocytes (Winblad et al., 1966;

Bradford et al., 1974). Intestinal perforation and gastrointestinal hemorrhage may rarely occur as a consequence of ulceration (Bradford et al., 1974; Moeller and Burger, 1985). There is some evidence for involvement of *Y. enterocolitica* and *Y. pseudotuberculosis* in granulomatous appendicitis, a histopathological diagnosis made in 0.1–2% of appendectomies (Lamps et al., 2001). The PCR for *Yersinia*-specific targets (either *Y. pseudotuberculosis* or *Y. enterocolitica*) was positive in 25% of a series of appendectomy specimens containing granulomas (Lamps et al., 2001).

Primary *Y. enterocolitica* peritonitis secondary to liver disease with infected ascites (Reed et al., 1997) has also been reported. *Yersinia enterocolitica* has been associated with intussusception (Burchfield et al., 1983; Winesett et al., 1996). Chronic and relapsing gastrointestinal disease with symptoms lasting for several years has been reported (Hoogkamp-Korstanje et al., 1988) where *Y. enterocolitica* could not be cultured but was persistently demonstrated by immunofluorescence in the intestinal mucosa and associated lymph nodes.

SYSTEMIC DISEASE *Septicemia* Iron-overloaded patients (e.g., those with thalassemia [Chiu et al., 1986; Adamkiewicz et al., 1998], sickle cell disease [Blei and Puder, 1993], or hemochromatosis [Prentice et al., 1991]), patients on chronic hemodialysis (Boelaert et al., 1987), those following acute iron supplement overdose (Bouza et al., 1980; Melby et al., 1982; Prentice et al., 1991), those with liver disease (Bouza et al., 1980) or diabetes (Bouza et al., 1980), and the elderly are at increased risk of a septicemic illness with a fatal outcome (Bullen et al., 1991; Prentice et al., 1991; Other putative or confirmed virulence factors, iron acquisition systems). It has been estimated that patients with, for example, β -thalassemia, are 5000 times more likely to have nonenteric *Y. enterocolitica* infection than the general population (Adamkiewicz et al., 1998). Medical interventions associated with systemic *Y. enterocolitica* infection include the use of the iron-chelating agent desferrioxamine (Robins-Browne and Prpic, 1983; Hoen et al., 1988), which provides an additional risk beyond that of the underlying iron-overload (Boyce et al., 1985) by virtue of *Y. enterocolitica* growth stimulation (Robins-Browne and Prpic, 1985a) and host immunosuppression (Autenrieth et al., 1994b). Conjugation of desferrioxamine with starch may provide a safer chelating agent (Schubert and Autenrieth, 2000a).

A low-grade bacteremia may result in seeding of particular intravascular foci producing a continuous bacteremia. Mycotic aneurysm due to *Y. enterocolitica* is a disease of middle aged and

elderly men (Plotkin and O'Rourke, 1981; Tame et al., 1998) who in most cases have bacteremia without any of the above risk factors for systemic yersiniosis. *Yersinia enterocolitica* (particularly serogroup O:9; La Scola et al., 1997) may be a more common cause of mycotic aneurysm (Prentice et al., 1993) than other better-recognized vasculotropic bacteria (Buckels et al., 1985) such as *Salmonella* and *Brucella* species. Serodiagnostic crossreactions (Weynants et al., 1996) between *Y. enterocolitica* serogroup O:9 and *Brucella* may account for previous associations between mycotic aneurysms and *Brucella* species (La Scola et al., 1997). Multiple mycotic aneurysms due to *Y. enterocolitica* requiring successive operations in the same patient have been described (Donald et al., 1996). Endocarditis is also recognized (Appelbaum et al., 1983; Giamairellou et al., 1995) and has now been reported from a total of 12 patients in the literature (Brouqui and Raoult, 2001), with no obvious serotype association.

Other Acute Extraintestinal Conditions Encephalopathy has been associated with *Y. enterocolitica* O:3 infection in a 10-year-old girl (Berner et al., 1998). Cellulitis has been associated with septicemia (Righter, 1981). Osteomyelitis of the tibia has been reported in a patient with Gaucher's disease without associated bacteremia (Fisch et al., 1989), and osteomyelitis with meningitis has also been reported (Casey et al., 1987). *Yersinia enterocolitica* infection of a prosthetic hip 15 years after insertion has been reported (i.e., presumed hematogenous spread; Hansen et al., 1989).

Blood Transfusion Severe, often fatal reactions after the transfusion of blood contaminated with environmental bacteria were well-recognized risks in the early days of blood transfusion (Braude et al., 1952). Single-unit, closed collection systems greatly reduced environmental contamination of donated blood (Walter et al., 1957) but have not eliminated the risk of contamination with *Y. enterocolitica* (Wagner et al., 1994). Since the first description in 1975 from The Netherlands (Bruining and De Wilde-Beekhuizen, 1975), over 35 cases have been reported worldwide (Hogman and Engstrand, 1996b). Common features of most reports include the refrigerated storage of whole blood or red cell concentrates for over three weeks before transfusion and serological evidence of donor infection with *Y. enterocolitica* at the time of donation (Prentice, 1992b; Hogman and Engstrand, 1996b). Recipients develop fever, respiratory distress, hypotension, and in some cases disseminated intravascular coagulation (Tipple et al., 1990; Anonymous, 1997). On standard investigation of

the transfusion reaction, large numbers of *Y. enterocolitica* are found in the remains of the transfused unit of blood, and the organism is grown from the recipient's blood (Prentice, 1992b; Hogman and Engstrand, 1996b). Over 50% of such reactions prove fatal (Tipple et al., 1990; Prentice, 1992a; Anonymous, 1997).

Experimental inoculation of small numbers of *Y. enterocolitica* (10–100 colony forming units [cfu]/ml) into units of whole blood (Stenhouse and Milner, 1982; Pietersz et al., 1992; Gibb et al., 1994) or red cell units (Arduino et al., 1989; Pietersz et al., 1992) stored at 4°C show a growth curve that passes through a lag phase lasting 7–10 days before a phase of exponential growth that after 2–3 weeks yields a concentration of 10⁸ cfu/ml. This proliferation is accompanied by the presence in the red cell unit of endotoxin levels that are fatal in animal models (Arduino et al., 1989; Hastings et al., 1994; Anonymous, 1997). Transfusion of such a contaminated unit would produce severe shock as seen in the clinical case reports. The presumed mechanism of introduction of the organism to the unit is a low-grade bacteremia in the donor at the time of donation (Tipple et al., 1990; Hogman and Engstrand, 1996b). A key property is clearly that *Y. enterocolitica* is a psychrotroph: optimal growth temperature is above 20°C (i.e., a mesophile) but capable of growth at 4°C. Although (in general) platelets are far more commonly contaminated with bacteria than other blood components (1 in 2000 units of platelets is bacterially contaminated; Wagner et al., 1994), they are stored at 20–25°C with a shorter conservation period and there has only been one reported case of *Y. enterocolitica* sepsis following platelet transfusion (Kuehnert et al., 1997).

Experiments also suggest a role for complement in restricting *Y. enterocolitica* growth in the lag phase (Gibb et al., 1994) and in eliminating small inocula of *Y. enterocolitica* (<10² cfu/ml) from donated blood (Pietersz et al., 1992). This could be maximized by leaving units of whole blood at 18–24°C for at least 6 hours after donation before further fractionation and refrigeration (Pietersz et al., 1992) because this temperature (unlike 4°C) allows complement to be active and renders *Y. enterocolitica* serum-sensitive (Gibb et al., 1994) owing to a decrease in expression of plasmid genes induced at 37°C (Chiesa and Bottone, 1983). Unfortunately these conditions promote the growth of *Pseudomonas fluorescens* (Gibb et al., 1995), another psychrotrophic organism, which is a leading cause of bacterial contamination of blood products (Wagner et al., 1994). White cells have been shown to remove inoculated bacteria from donor blood (Hogman et al., 1991), presumably by phagocytosis. Because phagocytic cells lyse after

14 days storage (Hogman et al., 1992), phagocytosed but intracellularly surviving bacteria could contribute to appearance of *Y. enterocolitica* in donated blood after this time (Hogman et al., 1992). A role for white cells in *Y. enterocolitica* survival is suggested by the ability of white blood cell filtration after incubation at 22°C to remove inoculated *Y. enterocolitica* from stored blood (Hogman et al., 1992; Pietersz et al., 1992) and enhanced growth of *Y. enterocolitica* seen on inoculation into leucodepleted blood (Hogman et al., 1992).

It has been suggested (Gibb et al., 1996) that the widespread introduction of additive solutions, which prolong the viability of red cells, into blood transfusions in the 1980s was associated with the emergence of this phenomenon. This could have had indirect effects by allowing prolongation of storage well below the observed lag phase and direct effects because of reduced complement-mediated killing of contaminating *Y. enterocolitica* in additive-containing blood (Gibb et al., 1996). This hypothesis is disputed (Hogman, 1996a). The lack of reports of *Y. enterocolitica* serovar O:8 in transfusion-related incidents has been linked (Bottone, 1997) to more rapid loss of complement resistance at lower temperatures in this bioserovar compared to other pathogenic bioserovars of *Y. enterocolitica* (Chiesa and Bottone, 1983). The absence of reports of transfusion-related *Y. pseudotuberculosis* sepsis may be similarly related to differences in complement resistance. In this organism, unlike *Y. enterocolitica*, serum resistance is not a plasmid-dependent property (Perry and Brubaker, 1983). However, *Y. enterocolitica* 8081 (a serovar O:8 strain) and *Y. pseudotuberculosis* strains of serovar II, III and V have been shown to grow well at 4°C in units of whole blood for transfusion (Malbrunot and Guiyoule, 1990). Other factors, e.g., less prevalent infection with these organisms or less frequent asymptomatic bacteremia, could account for the paucity of transfusion reactions observed.

Control measures have been difficult to devise and cases continue (Strobel et al., 2000) despite widespread recognition of the problem. Techniques such as autologous transfusion that prevent transmission of other blood-borne infections do not prevent this syndrome (Sire et al., 1993; Haditsch et al., 1994). Donor exclusion by screening for recent gastrointestinal symptoms would exclude up to 6% of donors (Grossman et al., 1991) and would impose an unacceptable restriction on the blood supply without excluding risk from asymptomatic donors (McDonald et al., 1996). Reduction in the storage period of whole blood and red cells to less than 25 days would have implications for the blood supply (Hoppe, 1992) and would not eliminate risk.

Individual testing of units immediately after collection, in parallel with other tests for blood-borne diseases, would require very sensitive assays to detect the small numbers of organisms capable of causing the problem, and testing immediately prior to transfusion would mean introducing an extra step in the transfusion process. Either of these strategies would have major cost and logistic implications. A recent international symposium was unable to suggest a simple method for the elimination of this problem (Klein et al., 1997). There is no international consensus (Reesink et al., 1993) on measures to maximize bactericidal action of whole blood as indicated above. Currently some countries (e.g., the Netherlands and Ireland) practice rapid cooling of donated whole blood to 20–22°C followed by an overnight hold at that temperature before component separation and leucocyte filtration (Reesink et al., 1993). Other countries (e.g., the United Kingdom and United States) do not have this as national policy (Reesink et al., 1993). There have been no cases reported via the (<http://www.shot.demon.co.uk>{Serious Hazards of Transfusion scheme}) in the United Kingdom since leucodepletion of all units commenced in November 1999.

A major factor complicating development of preventive measures has been the rarity of the syndrome. Most effort in finding and reporting cases has been in the United States where an estimate of one *Yersinia*-associated RBC transfusion reaction per 500,000 units has been made (United States General Accounting Office, 1997). Other countries have reported much higher rates, e.g., 1 in 65,000 in New Zealand (Theakston et al., 1997) where *Y. enterocolitica* is a leading enteric pathogen (Fenwick and McCarthy, 1995). Concern that under-reporting of *Y. enterocolitica* and other bacteria-associated blood transfusion reactions was occurring in the United States led to a prospective study organized by the United States Centers for Disease Control Hospital Infections Program (Anonymous, 1997). The data from BaCon Study (Assessment of the Frequency of Blood Component Bacterial Contamination Associated Transfusion Reaction), conducted from 1997–2000, are currently being analyzed.

POST-INFECTIVE PHENOMENA Reactive arthritis is a sterile, usually self-limiting arthritis following a gastrointestinal, urogenital or pharyngeal infection (Sieper and Braun, 1999a; Immunology, paragraph reactive arthritis) often accompanied by other complications such as erythema nodosum, keratoderma, uveitis or conjunctivitis (Gaston, 2001). Typically, an asymmetric arthritis of the lower limbs is seen, and 50% of the patients are human leukocyte antigen (HLA)-

B27 positive (Sieper et al., 1996). Because of some shared symptoms, pathology, and probable post-infective etiology, reactive arthritis is grouped together with inflammatory bowel disease associated arthritis, psoriatic arthritis, undifferentiated arthritis and ankylosing spondylitis as a spondyloarthropathy (arthropathy affecting the axial skeleton; Gaston, 2001) even though in reactive arthritis the axial skeleton and sacroiliac joints are generally less commonly involved than the lower limbs (Gaston, 2001).

Yersinia enterocolitica is one of the most common microorganisms associated with reactive arthritis (Valtonen et al., 1985) or undifferentiated arthritis (a similar clinical picture where there is no obvious prior infection; Van der Heijden et al., 1997; Fendler et al., 2001) and is linked with 18–25% of cases in these series. This association is supported by detection of high titers of circulating IgA and IgG antibodies to *Y. enterocolitica* and *Y. pseudotuberculosis* (Fendler et al., 2001), detection of *Y. enterocolitica* antigens in colonic and synovial tissue (Hoogkamp-Korstanje et al., 1988; Granfors et al., 1989; Van der Heijden et al., 1997), and cloning of *Y. enterocolitica*-specific T-cells from the synovial tissue (Van der Heijden et al., 1997) of patients with reactive or undifferentiated arthritis. Culture or detection of *Y. enterocolitica* DNA by PCR in synovial tissues in reactive or undifferentiated arthritis has been mainly negative (Nikkari et al., 1992; Braun et al., 1997) despite the repeated detection of *Y. enterocolitica* antigens in these tissues (Viitanen et al., 1991; Nikkari et al., 1992; Van der Heijden et al., 1997). The PCR amplification of a 16S rRNA gene segment with a closest fit to *Y. enterocolitica* has been reported from synovial fluid in one patient with arthropathy (Wilkinson et al., 1999).

A consensus view (Sieper et al., 2000) is that the presence of living bacteria in synovium is not a requirement for reactive arthritis, but the continuing presence of bacterial antigens in the joint and in circulating white cells (Granfors et al., 1998) is part of the process. The precise relationship between activated synovial or circulating T cells specific for bacterial antigens, host HLA-B27 status, and the disease process is not clear (Sieper et al., 2000; Gaston, 2001). The absence of an active infection with viable bacteria accords with the lack of improvement over placebo shown in controlled trials of ciprofloxacin therapy for reactive arthritis due to *Yersinia* (Sieper et al., 1999b) or reactive arthritis in general (Toivanen et al., 1993; Sieper et al., 1999b). However, antibiotic therapy has been useful in chronic relapsing gastrointestinal disease caused by *Y. enterocolitica* (Hoogkamp-Korstanje et al., 1988) and in one reactive arthritis trial, ciprofloxacin eliminated *Y. enterocolitica* antigen from

colonic biopsies and achieved a nonsignificant trend to more rapid remission than placebo (Hoogkamp-Korstanje et al., 2000).

Raised antibody titers to *Y. enterocolitica* are seen in patients with autoimmune thyroid disorders (Bech et al., 1974), partly due to thyrotrophin (TSH) binding sites on *Y. enterocolitica* recognized by these autoantibodies (Heyma et al., 1986). It is not thought that *Y. enterocolitica* infection is a major factor in triggering thyroid disease (Toivanen and Toivanen, 1994).

Bacteriological Diagnosis of *Y. enterocolitica* (Georges Wauters)

Non-pestis yersiniae include two pathogenic species: *Y. pseudotuberculosis*, genetically related to *Y. pestis*, and *Y. enterocolitica*. Besides the latter species, several strains are known as “*enterocolitica*-like organisms” and were later assigned to the so-called “related species”: *Y. intermedia*, *Y. frederiksenii*, *Y. kristensenii*, *Y. aldovae*, *Y. rohdei*, *Y. mollaretii* and *Y. bercovieri*. *Yersinia ruckeri* has been tentatively included in the genus *Yersinia*, but its taxonomic position is controversial (Taxonomy).

Non-pestis *Yersinia* strains exhibit the general characteristics of Enterobacteriaceae, being fermentative, oxidase-negative, Gram-negative rods and growing on ordinary media. Except for *Y. ruckeri*, common features of these species are the presence of urease, with very few exceptions. They lack lysine decarboxylase, arginine dihydrolase, phenylalanine deaminase and do not produce H₂S on Kligler agar.

They have also common characteristics with regard to growth temperature. Optimal growth occurs at 30–32°C rather than 37°C. However, some properties (like motility and acetoin production) are only detected when the incubation temperature is below 30°C. Other biochemical features (like urease and some assimilation and fermentation reactions) may also be weak and delayed, or even negative at 37°C. These organisms are psychrophilic and are able to grow, although slowly, at 4°C. Conversely, in pathogenic species, most virulence factors are expressed only at 37°C. The choice of the incubation temperature therefore depends on the purpose of the bacteriological investigation.

ISOLATION OF *Y. ENTEROCOLITICA* *Yersinia enterocolitica* can be recovered on some selective media currently used for stool culture, e.g., Salmonella-Shigella (SS) and deoxycholate (DCL) agar, but colonies are small and when incubated at 37°C, require 48 h for optimal detection. A better way is to incubate overnight at 37°C followed by an additional 24 h at room temperature. Media containing sucrose such as

deoxycholate citrate lactose sucrose (DCLS) agar and Hektoen agar should not be used since *Y. enterocolitica* acidifies sucrose hindering any detection of suspect colonies. More specific isolation media may be considered:

CIN (cefsulodin, irgasan, and novobiocin) agar is widely used for isolation of the organism from feces and food (Schiemann, 1979). Optimal incubation temperature should be 30–32°C, but 37°C and room temperature are also suitable. Colonies are quite typical after 24 h of incubation at 30°C; they have a “bull’s eye” appearance with a small red center surrounded by a colorless area. After 48 h, they are larger, the red center becomes diffuse, and they are readily mistaken for other enterobacteria, e.g., *Citrobacter*. Therefore, prolonged incubation of CIN at 30°C is of little value.

SSDC (SS agar supplemented with 1% deoxycholate and 0.1% of CaCl₂; Wauters et al., 1988a) must be incubated at 30–32°C for 24–48 h, and not at 37°C. Colonies are small and colorless after 24 h of incubation, but since the medium is highly inhibitory, colonies of other bacteria may be even smaller. This medium is mainly useful when combined with an enrichment method.

ENRICHMENT PROCEDURES Cold enrichment was first advocated to increase the isolation rate of *Y. enterocolitica* from feces and food. Specimens are suspended in phosphate buffer pH 7.6 and allowed to stay 1–3 weeks at 4°C (Ahvonen, 1972; Eiss, 1975; Toma and Deidrick, 1975). A subculture is made onto CIN or SSDC agar, with or without a KOH treatment of the inoculum, as described by Aulisio et al. (1980). For feces, however, this method is not very useful because of the long delay. Moreover, cold enrichment mainly improves the recovery of nonpathogenic *Yersinia* biotypes and species (Van Noyen et al., 1980).

ITC (irgasan, ticarcilin, and chlorate) broth incubated for 2 days at 24°C results in a significant increase of biotype 4 (serotype 3) strains, but is not suitable for other bioserotypes. Use of SSDC rather than CIN agar is recommended for subculturing from ITC broth. The usefulness of this enrichment is particularly obvious in the detection of *Yersinia* in food (Wauters et al., 1988a).

IDENTIFICATION Any colony displaying presumptive characteristics of *Yersinia* should be carefully and completely identified, since biotypes of *Y. enterocolitica* may have a different pathogenic relevance and some related species may closely resemble *Y. enterocolitica* sensu stricto. The main differential characteristics of *Yersinia* species are reported in Table 1. Four key-tests allow the dif-

ferentiation of *Y. enterocolitica* sensu stricto from related species. *Yersinia enterocolitica* is sucrose positive and rhamnose negative and does not assimilate citrate or mucate. At least one of these tests gives an opposite result in the other species.

Commercial systems like API 20E and ID 32E usually achieve a reliable identification of *Y. enterocolitica*, but to a lesser extent of the related species.

Yersinia enterocolitica strains have been classified into five biotypes, the first of which is subdivided into biotypes 1^A and 1^B. The biotype scheme is based on the following properties: Tween esterase, rapid esculin hydrolysis (less than 24 h), pyrazinamidase, indole production, acid from xylose and trehalose, and nitrate reduction (Wauters et al., 1987; Table 2).

More than 75 somatic antigens (O-antigens) have been described in *Y. enterocolitica* and the related species (Wauters et al., 1991). There are also a large number of flagellar antigens that are not currently used in antigenic typing. Different *Yersinia* species and biotypes may share common O-antigens. In *Y. enterocolitica*, there is some correlation between biotype, antigenic pattern, and ecological behavior. Strains that are pathogenic for man or animals belong to biotypes 1^B, 2, 3, 4 and 5 and possess only a limited number of O-factors. Biotype 1^B includes strains mainly possessing antigens O:8, O:13 and O:21. Biotype 2 consists of strains possessing antigens O:9 (which share antigenicity with *Brucella*) and O:5,27. Biotype 3 includes factor O:1,2,3 and more recently the Voges-Proskauer (VP)-negative Asiatic O:3 strains. In biotype 4, only serotype O:3 is found (the most widespread human pathogen), and in biotype 5, only serotype O:2,3 (in animals). Strains of biotype 1^A are nonpathogenic, ubiquitous, and are often found in food and in the environment. Hence, they may be occasionally encountered in the digestive tract of animals and humans. They carry a large variety of O-antigens of which O:5, O:6 and O:7,8 are the most common. Although some O antigens like O:3, O:9 or O:8 are regularly found in pathogenic strains, they should not be considered as specific since they sometimes occur in other species or nonpathogenic biotypes, e.g., O:8 in *Y. bercovieri* or in biotype 1^A, O:9 in *Y. frederiksenii*, O:1,2,3 in biotype 1^A, O:3 in *Y. mollaretii*, etc. Therefore, serotyping should not be performed as a single procedure on suspected isolates but only after appropriate species and biotype determination.

VIRULENCE AND PATHOGENICITY MARKERS OF *Y. ENTEROCOLITICA* The pYV virulence plasmid of *Y. enterocolitica* plays an important part in the pathogenicity of the organism and encodes

several properties that can be detected by in vitro tests (pYV virulence plasmid). Some methods for detecting pYV are easy to perform routinely and most are correlated with the production of the YadA protein. The following are the most useful:

Calcium dependency at 37°C can be detected on Congo red-magnesium oxalate (CR-MOX) agar (Riley and Toma, 1989). Plasmid-bearing bacteria produce small red colonies.

Autoagglutination of pYV⁺ strains in broth at 37°C. Although the test is very simple, it is not as reliable as others.

Agglutination of the strain grown on tryptic soy agar at 37°C by the phytoagglutinins of *Mangifera indica* (Wauters et al., 1995) or *Persea americana*.

Agglutination of the strain grown on tryptic soy agar by an antiserum against the YadA protein, which is not commercially available (Sory et al., 1990).

The pYV plasmid can be lost after a few subcultures, and it might be important to assess the potential pathogenicity of a strain, even if plasmidless.

Two biochemical tests, pyrazinamidase and rapid esculin hydrolysis, may offer a screening method in this respect. Strains that are pyrazinamidase and/or esculin positive are likely to be nonpathogenic (biotype 1^A and related species). Strains that are pyrazinamidase and esculin negative are likely to be pathogenic (biotype 1^B, 2, 3, 4 and 5).

Moreover, potential pathogenic strains, even after losing the virulence plasmid, produce at 37°C, but only on acid media, a fibrillar protein called “mucoid *Yersinia* factor” or Myf (Other putative or proven virulence factors). It can be detected in strains grown at low pH and 37°C by an agglutination test using an anti-Myf serum (Leiva et al., 1995).

Recently Fenwick et al. described *Y. enterocolitica*-like strains with atypical characteristics such as a negative ornithine or acid production from melibiose. They possess two new somatic antigens designated “O:77” and “O:78.” They

exhibit a borderline genomic relationship with *Y. enterocolitica*. Virulence markers are negative and no pathogenicity has been found. Up to now, these strains were only isolated in New Zealand (Fenwick et al., 1996).

DIFFERENTIATION OF *Y. enterocolitica* FROM RELATED *Yersinia* SPECIES These species (like *Y. enterocolitica* biotype 1^A) are frequently isolated from food and are also found as transient organisms in the digestive tract of humans or animals. They should be carefully differentiated from *Y. enterocolitica* sensu stricto (Bercovier et al., 1980a), especially from the pathogenic strains, since the related species have no or little clinical relevance. Out of more than 200 strains isolated from human stools, *Y. frederiksenii* and *Y. bercovieri* together accounted for 76% of the isolates; the remaining 24% were *Y. kristensenii*, *Y. intermedia*, *Y. mollaretii* and *Y. rohdei*.

Y. intermedia This species has been described by Brenner et al. (1980a) and displays strong metabolic activity: many carbohydrates (e.g., rhamnose, melibiose, raffinose, and α -methyl-glucoside) are acidified, and Simmons' citrate is positive (Table 1). However, some variability is observed in these tests, allowing 8 biotypes to be identified within the species (Brenner et al., 1980a). Except for some rare isolates from stools, a few strains have been recovered from extra-intestinal sites in humans (Bottone, 1978; Farmer et al., 1985).

Y. frederiksenii *Yersinia frederiksenii* also has been described in 1980 by Ursing (Ursing et al., 1980), but this species is genetically heterogeneous, and phenotypic characteristics are also quite variable. *Yersinia frederiksenii* (unlike *Y. intermedia*) strains do not ferment melibiose and α -methyl-glucoside. Citrate and Tween-esterase give different results (Table 1). This is one of the related species most frequently encountered in humans.

Y. kristensenii The description of this species was done by Bercovier et al. in 1980 (Bercovier et al., 1980c). *Yersinia kristensenii* has few positive biochemical properties, ferments neither sucrose nor many other sugars, and never produces acetoin. The positive ornithine reaction and the lack of rhamnose acidification help avoid confusion with *Y. pseudotuberculosis*. Pyrazinamidase is often weak in this species, hampering the screening for pathogenic strains.

Y. aldovae Described in 1984 by Bercovier et al. (1984), this species, which is rhamnose positive but sucrose negative, has never been isolated in humans.

Y. rohdei Aleksic et al. described in 1987 (Aleksic et al., 1987) a new species, which is mucate negative like *Y. enterocolitica*, but citrate positive unlike the latter.

Y. mollaretii and *Y. bercovieri* These closely related species were described in 1988 by Wauters et al. (1988b). Acid production from fucose and sorbose are the only differences between the two species (Table 1). Among the related species, *Y. bercovieri* and *Y. mollaretii* are most similar to *Y. enterocolitica*. The main difference is the ability to assimilate mucate, which is not present in *Y. enterocolitica* sensu stricto. They can also be differentiated from the pathogenic *Y. enterocolitica* biotypes by a positive pyrazinamidase test. Another important feature is the lack of acetoin production, which is as a rule positive in pathogenic *Y. enterocolitica*, except in the VP negative variant of biotype 3.

It should be noted that *Y. bercovieri* is the second most prevalent *Yersinia* species in humans among the related species, just after *Y. frederiksenii*. It is frequently isolated from food as well. Most commercial identification systems do not include these species in their database and record them as *Y. enterocolitica*.

Y. ruckeri This fish pathogen (redmouth bacterium) has been included in the genus *Yersinia* by Ewing in 1989 (Ewing et al., 1978), but this inclusion is controversial (De Grandis et al., 1988a). The biochemical reactions of *Y. ruckeri* do not fit the general profile of *Yersinia* and some strains may be lysine and gelatin positive. Growth at 37°C is poor. The only report of a human isolate of *Y. ruckeri* is not fully documented and may be questionable (Richard, 1984).

Yersinia pseudotuberculosis

Epidemiology of *Y. pseudotuberculosis* (Hiroshi Fukushima)

HUMAN INFECTIONS *Yersinia pseudotuberculosis* has a wide distribution in most countries with cold climates and is recognized as an important causative agent of sporadic and epidemic human enteric diseases (Mair, 1965; Tsubokura et al., 1989; Table 3).

The main clinical manifestations of human infections in Europe (Clinical manifestations of *Y. pseudotuberculosis* infections) are fever and gastroenteritis (Winblad, 1967; Ahvonen, 1972; Aleksic et al., 1995; Table 4). Septicemic forms of *Y. pseudotuberculosis* infections are rare, but are frequent in patients with underlying disorders such as diabetes, hepatic cirrhosis or iron-overload (Ljungberg et al., 1995; Table 5).

In contrast, the clinical features of human infections in Japan (Sato et al., 1983; Fukushima et al., 1985b; Tsubokura et al., 1987), Far East Russia (Somov and Martinevsky, 1973), and Korea (Cheong et al., 1995) are not only gastrointestinal symptoms but also a variety of systemic manifestations such as fever, scarlatina-like rash, desquamation, erythema nodosum, and arthritis (Table 6 and Fig. 1). The major differences in clinical symptoms between Far Eastern and Western countries are rash and desquamation, which are not seen in Western patients but are common in the Far East. Moreover, in Japan approximately 10% of the infected children fulfill diagnostic criteria of Kawasaki disease, including coronary vasculitis (Baba et al., 1991). Acute renal failure, mostly tubulointerstitial nephritis, is also seen in these patients (Takeda et al., 1991; Cheong et al., 1995).

It appears that the difference in clinical manifestations of *Y. pseudotuberculosis* infection between the Far Eastern and Western countries is related to the heterogeneity in the distribution of *Yersinia pseudotuberculosis* superantigen (YPMa) and high-pathogenicity island (HPI).

In sporadic cases, the highest incidence of infection is in 1–5 year-old children, with a peak at 2 years of age (Sato, 1987a; Aleksic et al., 1995; Fig. 2).

The female : male ratio is 1 : 1 in Germany and Finland (Ahvonen, 1972; Aleksic et al., 1995) but 1:1.5 in Japan (Tsubokura et al., 1987).

The highest incidence is observed during the coldest months, regardless of the geographical areas (Mair, 1965; Fukushima et al., 1985b; Sato, 1987a; Tsubokura et al., 1987; Aleksic et al., 1995; Fig. 3).

Although small outbreaks attributable to *Y. pseudotuberculosis* in some families have been documented in Europe (Aleksic et al., 1995), large scale outbreaks of *Y. pseudotuberculosis* occurred mainly through consumption of vegetables or water contaminated with this organism in Japan (Inoue et al., 1984a; Fukumoto et al., 1987; Sanbe et al., 1987; Inoue et al., 1988; Nakano et al., 1989; Tsubokura et al., 1989; Toyokawa et al., 1993) and Far East Russia (Shiozawa et al., 1988; Fukushima et al., 1998b), and in Finland (Tertti et al., 1984; Table 7).

DISTRIBUTION OF THE SUBGROUPS OF *Y. PSEUDOTUBERCULOSIS*

Serotypes of *Y. pseudotuberculosis* There are 21 different serotypes of *Y. pseudotuberculosis*: O:1a, 1b, 1c, 2a, 2b, 2c, 3, 4a, 4b, 5a, 5b, 6, 7, 8, 9, 10, 11, 12, 13, 14 and 15 (Tsubokura and Aleksic, 1995; Nagano et al., 1996; Table 8).

In Western countries (Europe, Australasia and North America; Mair, 1965; Hubbert, 1972;

From Tsubokura and Aleksic (1995) and Nagano et al. (1997).

Bissett, 1979; Toma, 1986; Aleksic et al., 1995; Fig. 4), serotypes O:1a, 1b, 2a, 2b, 3, 5a and 6, of which serotypes O1a and 1b are dominant, have been isolated from clinical samples (Table 3).

In the Far East (Fukushima et al., 1985b; Fukushima et al., 1987; Tsubokura et al., 1989; Sato and Komazawa, 1991; Cheong et al., 1995; Fukushima and Gomyoda, 1995a), serotypes O1b, 2a, 2b, 3, 4a, 4b, 5a, 5b and 15, of which serotypes O4b and 5b are dominant, have been isolated from clinical samples (Tables 3 and 9).

In the Far East, serotypes O:7 to O:14 have been isolated only from wild animals and the

environment but never from clinical samples (Fukushima et al., 1990a; Fukushima et al., 1995c; Fukushima and Gomyoda, 1991b; Zheng et al., 1995; Nagano et al., 1997b).

The pathogenicity of *Y. pseudotuberculosis* depends on the presence of a 70-kb virulence plasmid termed “pYV” (Gemski et al., 1980). This plasmid is essential for virulence and its presence differentiates pathogenic from non-pathogenic *Yersinia* (pYV virulence plasmid). The pYV is found in almost all serotypes O:1a to 6, 10 and 15 but not in serotypes O:7, 8, 9, 11, 12, 13 and 14 (Fukushima et al., 1990a; Fukushima et al., 2001b; Kaneko et al., 1991; Fukushima and Gomyoda, 1995b; Zheng et al., 1995; Nagano et al., 1996). Additionally, a pathogenicity island termed “high-pathogenicity island” (HPI; Carniel, 1999; High Pathogenicity Island) and/or chromosomally encoded novel superantigenic toxins designated “*Y. pseudotuberculosis*-derived mitogen”: YPMa (Abe et al., 1993; Uchiyama et al., 1993; Ito et al., 1995; Yoshino et al., 1995a; Ueshiba et al., 1998; Carnoy et al., 2000), YPMb (Ramamurthy et al., 1997a), or YPMc (Carnoy and Simonet, 1999) are found in *Y. pseudotuberculosis* (Superantigens of *Y. pseudotuberculosis*).

Genetic Groups of Y. pseudotuberculosis and Their Geographical Distribution

The relationship between the presence of YPM and HPI in *Y. pseudotuberculosis* in 2235 strains collected all over the world (Fukushima et al., 2001b; Table 10 and Figs. 4–6), and restriction endonuclease analysis of pYV (REAP; Kaneko et al., 1991; Fukushima et al., 1994a; Fukushima et al., 1998b; Fig. 7) revealed that *Y. pseudotuberculosis* can be separated into six genetic groups.

YPMa⁺/HPI⁺: Far East The strains belong to serotypes O:1b, 3, 5a, 5b and 15 and are isolated from patients and wild animals in the Far East

Fig. 5. Geographical distribution of *Y. pseudotuberculosis*.

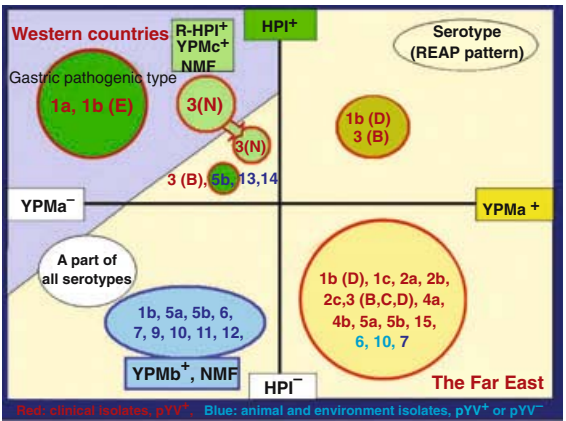

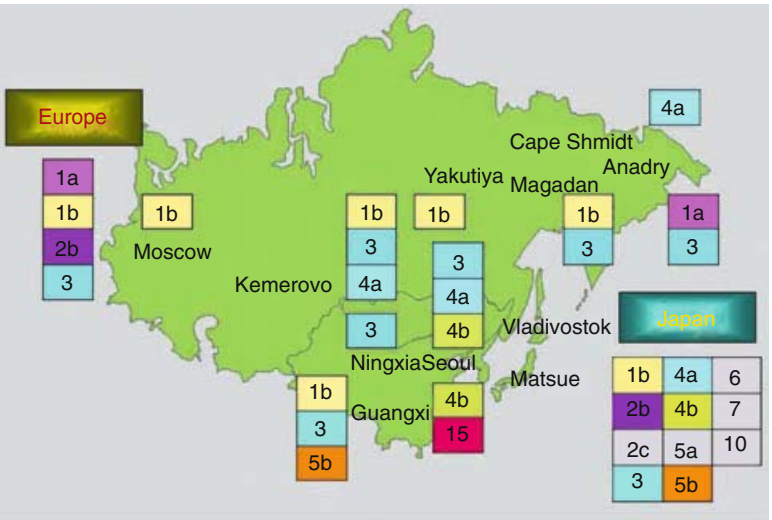

Fig. 6. Distribution of serotypes of *pYV+* in *Y. pseudotuberculosis*.

(Table 11). The *virF* gene was detected in 56% of the strains.

YPM-/HPI+: European Enteropathogenic Type
These strains are mostly from serotypes O:1a and 1b and are predominantly isolated from patients and wild animals in Western countries (Mair,

1965; Hubbert, 1972; Toma, 1986; Chiesa et al., 1993; Aleksic et al., 1995; Table 12). Five serotype O:1a strains were also isolated from reindeer and salmon in Far East Russia (Fukushima et al., 1998b). Eleven strains belonging to serotypes O:3, 5b, 13 and 14 from a patient and wild animals in the Far East were also in this group.

Fig. 7. Restriction endonuclease analysis of virulence plasmid DNA (REAP) patterns by *Bam* HI among serotypes isolated from various sources in eastern and western countries. From Fukushima et al. (1994a).

From Fukushima et al. (2001b).

Although three strains of serotypes O:13 and 14 from wild mice in China did not have pYV and were avirulent, one strain of serotype O:3 in this group was isolated from the sputum of a patient with a fever and pneumonia in China and was virulent for mice.

The *virF* gene was detected in 49% of the strains.

REAP patterns of serotypes O:1a (Fig. 8) and 1b (Fig. 9) strains isolated in Western countries are B and E, respectively, which differ from those isolated in the Far East.

A borderline geographical distribution of organisms between both areas, Europe and the Far East, is found west of Ural Mountains (Fukushima et al., 1998b).

This group is also present in Africa, Australasia and North and South America, and might have been unknowingly introduced by human carriers or in shipments of livestock from Europe in the late 1700s and early 1800s (Slee and Skilbeck, 1992; Mollaret, 1995; Fig. 10).

YPMa⁺/HPI⁺: Far Eastern Systemic Pathogenic Type This group (Table 13) includes many strains belonging to 16 serotypes (O:1b, 1c, 2a, 2b, 2c, 3, 4a, 4b, 5a, 5b, 6, 7, 10 and 15) from the Far East and three strains of serotype O:4a from horses in Denmark. Almost all (82%) Far Eastern strains belonged to this group. Strains of serotypes O:1b, 2a, 2b, 2c, 3, 4a, 4b, 5a, 5b and 15, of which serotypes O:4b and 5b are domi-

Abbreviations: YPMs, *Yersinia pseudotuberculosis* mitogens; and for other definitions, refer to footnote in Table 11.

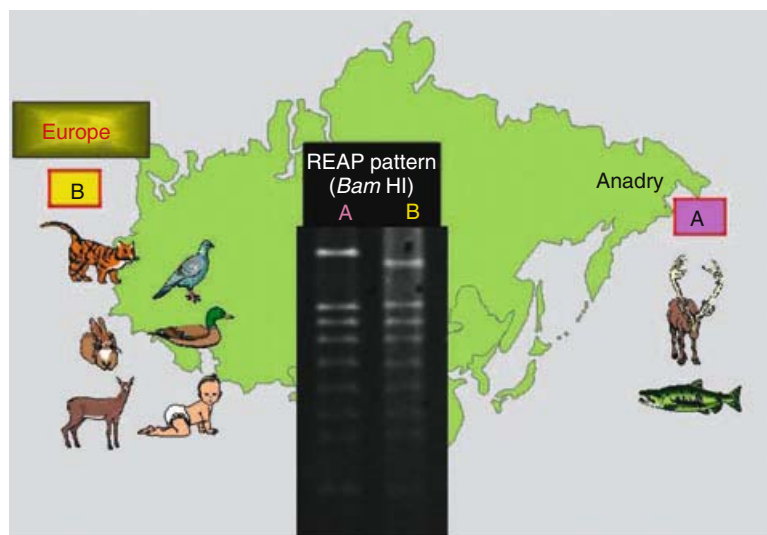

Fig. 8. Distribution of REAP (restriction endonuclease analysis of virulence plasmid DNA) patterns of *Y. pseudotuberculosis* serotype O:1a.

nant, were isolated from patients, pigs, wild animals and environments, while serotype O:6, 7 and 10 strains were isolated only from wild animals and the environment but never from clinical samples.

The *virF* gene was detected in 77% of the strains.

REAP patterns of serotype O:1b, 2b and 3 isolates in the Far East are different from

those of European isolates (Figs. 9, 11 and 12). REAP patterns of serotype O:1b, 3, 4a and 4b isolates in Korea and Russia were the same as those of Japanese isolates (Figs. 9, and 12–14). These data indicate that the origin of most *Y. pseudotuberculosis* in Japan might be the Far East region of the Eurasian continent. Spread of these organisms might have been facilitated by the connection of the

Fig. 9. Distribution of REAP (restriction endonuclease analysis of virulence plasmid DNA) patterns of *Y. pseudotuberculosis* serotype O:1b.

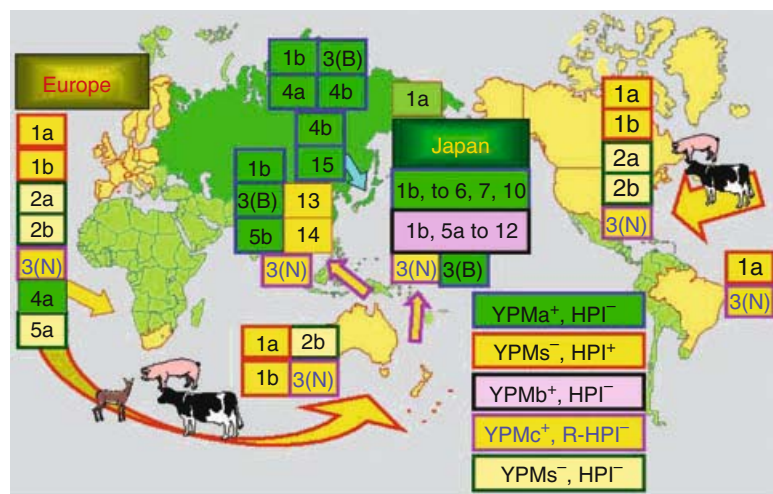

Fig. 10. Transmission of *Y. pseudotuberculosis* throughout the world.

islands of Japan to the Eurasian continent before the Ice Age.

YPMb⁺/HPI⁻: Nonpathogenic Japanese Strains Strains belonging to the YPMb⁺/HPI⁻ group are environmental isolates of serotypes O:1b, 5a, 5b, 6, 7, 9, 10, 11 and 12, and are nonpathogenic (Table 14). Those of serotype O:1b lacked pYV during stock culture and other serotypes naturally did not harbor the pYV. They were isolated from wild animals and the environment in Japan (Fukushima et al., 1990a; Nagano et al., 1997b).

YPMC⁺/R-HPI⁺: Low Pathogenic Strains These are all serotype O:3 strains isolated from patients and animals (pigs, monkeys and livestock in Western countries, but only pigs in the Far East; Table 15). One case of human infection with a strain of this group in Japan was characterized by a terminal ileitis without systemic symptoms

(Kanazawa et al., 1974). This is in contrast with human infections due to serotype O:3 belonging to the Far Eastern systemic pathogenic group YPMa⁺/HPI⁻, which is widely distributed among pigs and wild animals in the Far East.

The pathogenicity to mice of this group is lower than that of European and Far Eastern pathogenic type (Tsubokura et al., 1984). However, this group is clearly able to produce enteritis in cattle and sheep (Slee et al., 1988; Slee and Skilbeck, 1992).

This group is present in Australasia and North and South America and might have been unknowingly introduced by human carriers or in shipments of livestock from Europe in the late 1700s and early 1800s (Slee and Skilbeck, 1992). In the Far East, these strains may have been introduced by export of pigs and pork from European pig-producing countries to Japan (Fukushima et al., 1994a; Fig. 10), same as in the

From Fukushima et al. (2001b).

case of *Y. enterocolitica* (Fukushima et al., 1997).

Strains in this group do not ferment melibiose.

The *virF* gene was detected in 89% of the strains.

REAP pattern of this group is N, which is different from that of serotype O:3 strains isolated from wild animals and from half of the pigs (Fig. 12).

YPM⁻/HPI⁻ This group is composed of clinical strains and many environmental strains belonging to 15 serotypes (O:1b, 2a, 2b, 2c, 3, 4a, 4b, 5a, 5b, 6, 7, 10, 11, 13 and 15). All strains of serotypes O:2b and 5a in Western countries belong to this group (Fukushima et al., 2001b; Table 16).

The *virF* gene was detected in 50% of the strains.

Therefore, analysis of the distribution of these genetic groups suggests that *Y. pseudotuberculosis* forms two main branches that originated in the Far East and in Europe. European strains of *Y. pseudotuberculosis* belong mostly to the enteropathogenic group YPM⁻/HPI⁺ (serotypes O:1a and 1b) and to the low-pathogenic type

YPMc⁺/R-HPI⁺ (serotype O:3). In contrast, most Far Eastern strains belong to the YPMa⁺/HPI⁻ group (serotypes O:1b, 1c, 2a, 2b, 3, 4a, 4b, 5a, 5b, 6, 10 and 15), which cause systemic infections, and to the nonpathogenic type YPMb⁺/HPI⁻.

RESERVOIRS OF *Y. pseudotuberculosis* *Yersinia pseudotuberculosis* is widely distributed among mammals (farm animals, pets, and wild animals) and birds in most countries with cold climates (Tables 10 and 17). The bacterium is widely spread in the environment (soil, water, vegetables, etc.) contaminated by feces of infected wild animals, and can survive in water for long periods (Dominowska and Malottke, 1971). The principal reservoirs are rodents and birds for the YPM⁻/HPI⁺ and YPMa⁺/HPI⁻ groups (Mair, 1973; Fig. 15), farm animals such as pigs and ruminants for the YPMc⁺/R-HPI⁺ group (Slee and Skilbeck, 1992; Fig. 16), and moles for the YPMb⁺/HPI⁻ group (Fig. 17).

Strains of this group do not ferment melibiose.

YPM⁻/HPI⁺ Group Strains of serotypes O:1a and 1b in this group (Table 12 and Fig. 15) are

Table 16. Prevalence of YPM⁻/HPI⁻ *Y. pseudotuberculosis* strains.

Abbreviations: MF, melibiose fermenting strains; for other definitions, refer to footnote in Table 11.

From Fukushima et al., (2001b).

found in a wide variety of mammals and birds in Europe (Mair, 1965; Bercovier et al., 1978; Aldova et al., 1980; Weber and Knapp, 1981; Weber et al., 1983; Mackintosh and Henderson, 1984; Aleksic et al., 1995; Tables 18 and 19), Africa (Mollaret, 1995), Australasia (Henderson, 1983a; Henderson, 1984; Hodges et al., 1984; Slee et al., 1988; Slee and Skilbeck, 1992; Table 20), North America (Hubbert, 1972; Langford, 1972; Toma, 1986; Tables 21–23), and South America (Martins et al., 1998; Table 24). Some strains of serotype 1a were also isolated from reindeer and salmon in Far East Russia (Fukushima et al., 1998b).

Serotype O:1a and 1b strains have been isolated from farm animals (cattle, buffalo, horse, sheep, goat, domestic deer and pig), domestic pets (cat and dog), experimental animals (guinea pig, hamster and rabbit), commercially reared fur-bearers (chinchilla, mink and coypu), wild mammals (hare, rat, mouse, vole, shrew, beaver,

deer, cats, etc.), zoological animals (monkey, kangaroo, ocelot, etc.), domesticated birds (hen, turkey and duck) and wild birds (canary, pigeon, etc.; Mair, 1965; Mair, 1973; Hubbert, 1972; Langford, 1972; Hacking and Sileo, 1974). Hares and guinea pigs are most frequently affected. In France, serotype O1 strains were isolated from 25% of hares and from 2.5% of soil samples (Bercovier et al., 1978). Many cases of animal yersiniosis due to infection by this group have been recorded in Western Europe, Australasia, Brazil and the United States, e.g., cats (Mair et al., 1967; Allard, 1979; Spearman et al., 1979), cows (Mair and Harbourne, 1963; Jerrett and Slee, 1989; Welsh and Stair, 1993), goats (Karbe and Erickson, 1984), deer (Chapman et al., 1979), foxes (Black et al., 1996), hares (Wuthe et al., 1995), monkeys (Bronson et al., 1972; Chang et al., 1980; Rosenberg et al., 1980; Brack and Gatesman, 1991; Plesker and Claros, 1992), wild park animals (Welsh et al., 1992),

pustard (Kormendy et al., 1988), and turkey (Wallner-Pendleton and Cooper, 1983). In New Zealand with the practice of capturing wild deer and the subsequent establishment of farmed deer, yersiniosis due to these strains emerged as a major disease (Henderson, 1983a).

Strains of serotypes O:3 and 5b in this group are found among domestic rabbits in China (Zheng et al., 1995) and wild animals such as raccoons, dogs and martens in Japan.

YPMa⁺/HPI⁻ Group This group of strains (Table 13 and Fig. 15) is found in a wide variety of mammals and birds in the Far East: Japan (Hirai et al., 1974; Zen-Yoji et al., 1974; Tsubokura et al., 1976; Tsubokura et al., 1984; Yanagawa et al., 1978; Kaneko et al., 1979; Kaneko and Hashimoto, 1981; Fukushima et al., 1983; Fukushima et al., 1984b; Fukushima et al., 1985c; Fukushima et al., 1989b; Fukushima et al., 1990a; Hamasaki et al., 1989; Kaneuchi et al., 1989; Fukushima and

strains of serotype O:4a were also isolated from horses in Denmark.

These strains are found among:

Farm animals: mainly pigs (Zen-Yoji et al., 1974; Tsubokura et al., 1976; Fukushima et al., 1989b; Fukushima et al., 1990b), but also cows (Fukushima et al., 1983), goats (Tsubokura et al., 1984), guinea pigs, and rabbits in Japan, but not in farm animals in Western countries. Serotypes O:1b, 2b, 2c, 3, 4a, 4b, 5a and 5b strains were found in 3% of slaughtered pigs in Japan. Their cecal content contained 10^5 cells/g (Fukushima et al., 1989b). About 75% of serotype O:3 strains

Fig. 18. Raccoon dog. This omnivorous animal belonging to a canine family is found in Japan, Korea and China. Recently the population of raccoon dogs showed a tendency to increase in mountainous areas close to residences in Japan. They eat plants and prey upon small wild animals.

isolated from pigs in Japan belong to this genetic group (Fukushima et al., 2001b)

Domestic pets: cats (0.9–3.2% in Japan), dogs (1.6–3.2% in Japan; Yanagawa et al., 1978; Fukushima et al., 1984b; Fukushima et al., 1985c), and cockatoo (Sanekata et al., 1991). Dogs and cats are infected with this organism during the cold seasons and excrete up to 10^4 *Y. pseudotuberculosis* cells/g of feces (Fukushima et al., 1985c)

Wild mammals: raccoon dogs (14–42.3%; Fig. 18), hares, deer, martens, foxes, rats, mice, moles, wild boars, etc. (Fukushima and Gomyoda, 1991b; Inoue et al., 1991). Serotypes O:1b, 2b, 3, 4b and 5a strains were found in 0.2–3.6% of wild mice (Kaneko and Hashimoto, 1981; Fukushima et al., 1990a) and in 3% of barn rats (Kaneko et al., 1979) in Japan. Adult and newborn wild mice are the principal reservoir of these strains and are a source of contamination for other wild animals and humans in mountainous areas (Fukushima et al., 1990a). Wild mice may excrete up to 10^4 *Y. pseudotuberculosis* cells/g of feces (Fig. 19). Prevalence of *Y. pseudotuberculosis* is in wild mice begins with an infection of the naïve newborn population and then quickly spreads among the naïve adult mouse population (Kaneko and Hashimoto, 1982; Fukushima, 1991a).

Zoo animals (monkey, cape hyrax, etc.).

Domestic birds (hens).

Wild birds (wild duck, crows, bunting, wagtail, pigeon, seagulls, etc.; Fukushima and Gomyoda, 1991b; Inoue et al., 1991).

YPMc⁺/R-HPI⁺ Group This group (Table 15 and Fig. 16) is found in pigs, ruminant farm animals

Fig. 19. Excretion of *Y. pseudotuberculosis* in the feces of *Apodemus spe-ciosus* intragastrically inoculated with 10^9 cells. From Fukushima (1991a).

Fig. 20. Prevalence of genetic groups among *Y. pseudotuberculosis* serotype O:3 strains isolated from pigs in Japan.

(cows, cattle, buffaloes, sheep, goats, and domestic deer), and zoo animals such as monkeys in Western countries (Tables 18–22, and 24) but only in pigs in the Far East. All serotype O:3 strains from Western countries belong to this group (Mair et al., 1979; Toma, 1986; Saridakis et al., 1988; Slee et al., 1988; Slee and Skilbeck, 1992) but half of serotype O:3 strains from Japan belong to this group (Fukushima et al., 2001b; Fig. 20).

Many cases of yersiniosis in ruminants (cattle, buffaloes, sheep and domestic deer) have been

Fig. 21. Seasonal occurrence of *Y. pseudotuberculosis* serotype O:3 in sheep and cattle in Australia. From Slee et al. (Slee et al., 1988; Slee et al., 1992).

recorded in Australia (Slee et al., 1988; Slee and Skilbeck, 1992; Fig. 21), New Zealand (Henderson, 1983a; Henderson, 1984; Henderson and Hemmingsen, 1983b), and Brazil (Martins et al., 1998). This group is clearly able to produce enteritis in ruminants and is maintained in these animal flocks (Slee et al., 1988; Slee and Skilbeck, 1992). The infection in wild animals and birds is rare, but was recorded in wild mice and house rats in Czechoslovakia (Aldova et al., 1977; Urgeova and Lysy, 1995), in canaries in the United States (Hubbert, 1972), and in a wild bird in Canada (Toma, 1986). Thus, the ruminant

farm animals may be the principal reservoir of this group (Slee and Skilbeck, 1992).

YPMb⁺/HPI⁻ Group This group (Table 14 and Fig. 17) is found in 15% of moles, which represent the reservoir and excrete 10⁴ *Y. pseudotuberculosis* cells/g of feces (Fukushima et al., 1990a), and in river water (Fukushima, 1992; Fukushima et al., 1994b; Fukushima et al., 1995c) of the mountainous area of Japan. This group is also found in 1% of wild mice (which excrete less than 10² cells/g of feces), and was found in a marten.

YPMa⁺/HPI⁺ Group These strains (Table 11) are found in humans, rabbits, raccoon dogs, and deer in the Far East (Fukushima et al., 2001b). The epidemiology of this group awaits confirmation from investigations of more cases of human infections.

YPM⁻/HPI⁻ Group This group (Table 16) is found in a wide variety of mammals and birds in the Far East. The epidemiology and pathogenicity of this group also awaits confirmation.

TRANSMISSION Transmission of *Y. pseudotuberculosis* to humans and animals does not need a vector and occurs by contact with infected animals or by consumption of food (vegetables and meat) or water contaminated by animal reservoirs (Carniel and Mollaret, 1990; Figs. 15–17).

Yersinia pseudotuberculosis infection due to contaminated drinking water is frequent in mountainous areas of Japan and Korea, which have rainy weather, and where residents use unchlorinated water from wells, springs and streams.

In contrast, in Western countries, *Y. pseudotuberculosis* is rarely found in the environment, and infections occur through the consumption of greenstuffs contaminated by rodents and birds (Mair, 1965; Mair, 1973; Fukushima et al., 1998b). Moreover, contamination of pork with *Y. pseudotuberculosis* suggests that products from farm animals may also be a source of human infection (Fukushima, 1985a; Shiozawa et al., 1988).

Birds Wood pigeons, which are often grossly affected, have been shown to excrete huge numbers of viable organisms in their feces as they feed on green crops such as kale, cabbage and brussels sprouts (Mair, 1973), which may be heavily contaminated (Paterson and Cook, 1963). Contaminated seeds are probably also a source of infection for farm animals. In zoological gardens, contamination of food stores and water containers by rodents and birds (Mair, 1973) has been incriminated as the source of animal infections. In England, a *Y. pseudotuberculosis*

is serotype O1 strain was isolated from the feces of a man and from the excreta of his canary (Daniels, 1961).

House Rodents *Yersinia pseudotuberculosis* is found in house rats living in kitchens, stores, barns, warehouses, zoological gardens and slaughterhouses (Winblad, 1967; Aldova et al., 1977; Aldova et al., 1980; Kaneko et al., 1979; Mackintosh and Henderson, 1984; Fukushima et al., 1998b). Cereals, greenstuffs and water contaminated by excreta of infected rodents are a source of infections for farm animals and humans (Mair, 1973). In England, mice trapped in a birdhouse, which had suffered heavy losses from yersiniosis, were found to be carriers of *Y. pseudotuberculosis* (Mair, 1973). In Russia, the same type of *Y. pseudotuberculosis* strain was isolated from patients and from cabbages, onions, carrots, potatoes and beets stored at home, in stores or warehouses, and from peridomestic rodents captured in the same place (Fukushima et al., 1998b).

Wild Animals The parallel distribution of serotypes among isolates from humans, water and wild animals such as raccoon dogs and wild mice in Shimane and Okayama Prefectures in Japan demonstrates transmission to humans through water contaminated with excretion from *Y. pseudotuberculosis*-infected wild animals (Fukushima et al., 1987; Fukushima et al., 1991c; Inoue et al., 1988; Inoue et al., 1991; Sato and Komazawa, 1991; Figs. 22–25). Wild animals become infected both by preying on small wild animals infected with *Y. pseudotuberculosis* and by ingesting environmental substances contaminated with this bacterium. The question of whether the main source of infection with *Y. pseudotuberculosis* in mountainous areas is the raccoon dog or the wild mouse remains unclear (Fukushima and Gomyoda, 1991b).

In a human outbreak involving 128 patients in Okayama Prefecture, a *Y. pseudotuberculosis* strain having the same serotype as that isolated from patients was found in one third of the water samples that these patients drank. The presence of 0.2–630 *Y. pseudotuberculosis* cells/ml of untreated water was observed for at least two months in most cases. In three cases, the continuous contamination of the water with a strain of the same serotypes was observed for 12 months and then every year for four years and in another case two years later (Sato and Komazawa, 1991). In Shimane Prefecture, the identity of the distribution of REAP patterns among serotype O:1b and 4b strains isolated from humans, river water, and wild animals proves the transmission of *Y. pseudotuberculosis* by water in this mountainous area (Fukushima et al., 1991c; Fukushima and

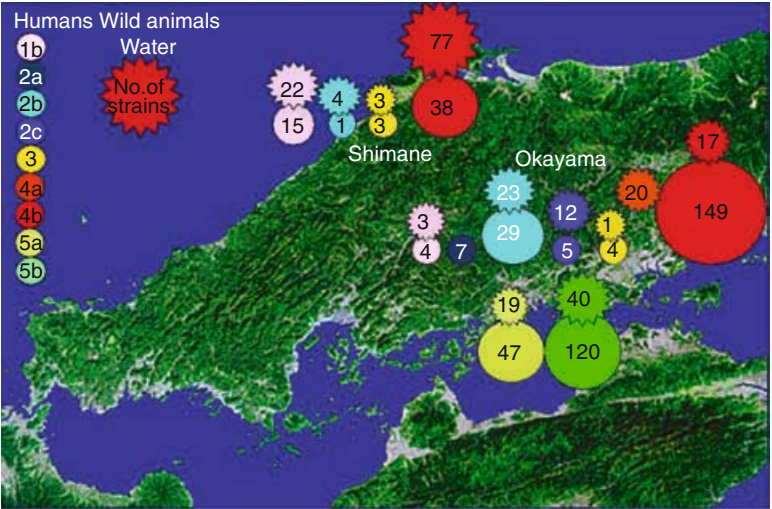

Fig. 22. Regional distribution of serotypes of *Y. pseudotuberculosis* isolated from humans, wild animals, and water between Shimane and Okayama Prefectures in Chugoku area, Japan.

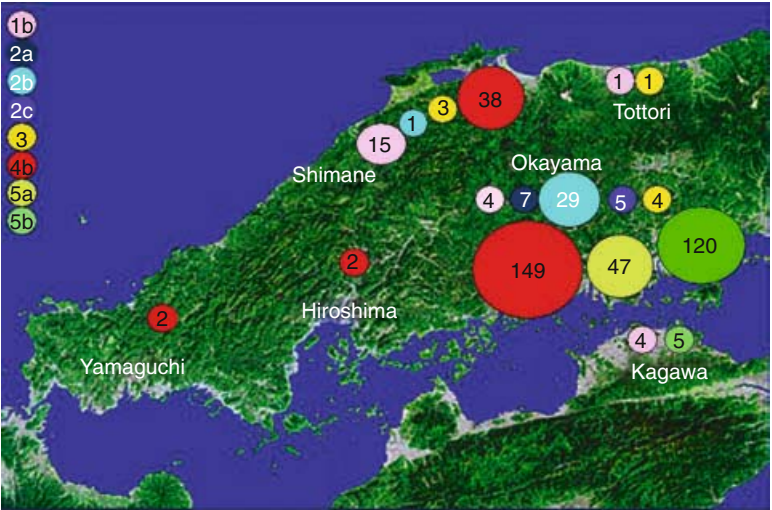

Fig. 23. Regional distribution of serotypes of *Y. pseudotuberculosis* isolated from patients in Chugoku area, Japan.

Fig. 24. Regional distribution of serotypes of YPM⁺ *Y. pseudotuberculosis* isolated from wild animals and water in Chugoku area, Japan.

Fig. 25. Parallel distribution of serotypes of *Y. pseudotuberculosis* among isolates from patients, animals and water samples in Shimane, Japan. From Fukushima et al. (1985c).

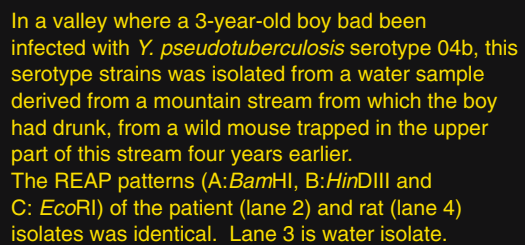

Gomyoda, 1995b). In one valley where a 3-year-old boy had been infected with *Y. pseudotuberculosis* serotype O:4b, a strain of the same serotype was isolated from a water sample of a mountain stream from which the boy had drunk, from a wild mouse trapped in the upper part of this stream, and from excreta of a deer near the mountainous area four years later (Fukushima et al., 1988a; Fig. 26). The REAP patterns of the mice, patient, water and deer isolates were identical. These data suggest the potential for transmission of *Y. pseudotuberculosis* to humans through water contaminated by wild animals carrying this species.

Domestic Animals Predators such as cats are infected directly by rodents and birds, and may thus constitute an important link between the natural reservoirs and man (Mair, 1973). The apparently healthy dogs infected with *Y. pseudotuberculosis* excrete 10^5 cells/g of feces (Fukushima et al., 1984b) and cats and dogs with diarrhea excrete 10^{7-8} cells/g of feces (Fukushima et al., 1989a). A laborer died of *Y. pseudotuberculosis* septicemia eight days after working in a garden where the soil had been fouled by excreta of an infected cat with diarrhea (Paul and Weltman, 1934). In Japan, a 1-year-old boy infected

with *Y. pseudotuberculosis* serotypes O:1b and 3, and his 3-year-old brother infected with *Y. pseudotuberculosis* serotype O:1b drank water from puddles in a garden in their housing area (Fukushima et al., 1989a). Strains with REAP patterns identical to those of the patients were isolated from the soil of the dried puddles, and from feces and the sandbox of a stray cat. This case provided evidence for the transmission of *Y. pseudotuberculosis* through water, sand, and soil contaminated by cat feces (Fig. 27).

Farm Animals The preponderance of serotype O:3 *Y. pseudotuberculosis* belonging to YPMc⁺/R-HPI⁺ group in ruminant animals and pigs was noted in Australia (Slee et al., 1988; Slee and Skilbeck, 1992; Fig. 21), New Zealand (Henderson, 1983a; Henderson, 1984; Henderson and Hemmingsen, 1983b; Table 20), Brazil (Martins et al., 1998; Table 24) and Canada (Toma, 1986; Table 22), and prevalence of this serotype in some Japanese pigs was noted (Tsubokura et al., 1984; Nagano et al., 1997a; Fukushima et al., 2001b; Table 25). In contrast, this serotype is uncommon in birds, rodents and other animals in which YPM⁻/HPI⁺ group in Western countries and YPMa⁺/HPI⁻ group in the Far East are usually predominant. This serotype O:3 was also iso-

[illegible]

groups in Western countries and the Far East, respectively. In Australia, serotype O:1 is occasionally isolated from sheep, suggesting that sheep are not a permanent reservoir for this bacterium (Slee and Skilbeck, 1992). In Japan, strains of the YPMa⁺/HPI⁺ group have been isolated from 4.5 to 6% of slaughtered pigs from 13% of pig farms (Fukushima et al., 1989b; Fig. 28). Retail pork meat was also found contaminated with strains of serotype O4b (Fukushima,

1985a; Shiozawa et al., 1988). When infected pigs were kept in a slaughterhouse lairage overnight, the oral cavity and skin of pigs from uninfected farms were contaminated with *Y. pseudotuberculosis* by contact and ingestion of bacteria from the floor of the lairage contaminated by the excreta of the infected pigs that harbored 10^5 cells/g of cecal contents (Tables 26 and 27). This contamination, occurring at the slaughterhouse, is of prime importance and should be taken into account to control the contamination of carcasses by *Y. pseudotuberculosis* (Fukushima et al., 1989b). This contamination extended to retail meat and the pork products (Fukushima et al., 1990b). *Yersinia pseudotuberculosis* serotype O:4b was isolated from raw pork (ground pork and tongue) from retail shops in Japan (Fukushima, 1985a; Shiozawa et al., 1988).

SEASONAL DISTRIBUTION The incidence of animal (Mair, 1965; Slee et al., 1988; Fukushima et al., 1990a; Slee and Skilbeck, 1992) and human diseases (Mair, 1965; Sato, 1987a; Fukushima and Gomyoda, 1991b; Aleksic et al., 1995) reach

a peak at the same time during late autumn and spring with cool and damp weather (Figs. 3, 21, 29, and 30). *Yersinia pseudotuberculosis* infection in wild mice begins with a contamination of the naïve newborn population in late autumn and then spreads among the *Y. pseudotuberculosis* naïve newborn and adult mice population during winter, spring and early summer (Kaneko and Hashimoto, 1982; Fukushima and Gomyoda, 1991b; Fig. 31). The seasonal incidence of this organism in farm animals, such as cattle, does not reflect the availability of susceptible host animals. There is, however, no evidence in the literature to indicate how *Y. pseudotuberculosis* survives over warm seasons when infection appears to be rare (Slee et al., 1988).

DIFFERENTIAL GEOGRAPHICAL DISTRIBUTION DUE TO MUTUAL EXCLUSION OF THE PATHOGENIC *YERSINIA* The plague bacillus, *Yersinia pestis*, has been one of the most devastating infectious agents in human history. Plague is essentially a disease of wild rodents that is transmitted to human and other animals by fleas (Carniel and Mollaret, 1990; Guiyoule et al., 1994). The closely related species *Y. enterocolitica* and *Y. pseudotuberculosis* are also pathogens of humans and cause zoonotic infections with the major reservoirs being rodents, domestic animals, and birds. Results of DNA hybridization studies have shown a close relation between *Y. pestis* and *Y. pseudotuberculosis* (Bercovier et al., 1980b). The immunity to plague after immunization with live *Y. pseudotuberculosis* is retained for a long time (Wake et al., 1978). This protection against *Y. pestis* is found in mice after oral administration of *Y. enterocolitica* serotypes O:3, O:5, 27 and O:9 (Alonso et al., 1980; Mazigh et al., 1984).

The enteropathogenic yersiniae, which are widespread among mammalian populations in various parts of the world, might serve as a silent but efficient barrier against *Y. pestis* spread from natural foci (Alonso et al., 1980). *Yersinia pseudotuberculosis* and *Y. enterocolitica* sero-

From Fukushima et al. (1990).

types O3 and O9 are widely distributed throughout Europe and Asia and may thus protect wild rodents against *Y. pestis* infection (Mollaret, 1995). The third plague pandemic began in the Yunnan region of China and reached Hong Kong in 1894. The existence of steamships and railways greatly favored a rapid spread of plague on the five continents and the colonization of new geographic areas (e.g., the United States, South America, South Africa, and Madagascar; Guiyoule et al., 1994; Mollaret, 1995). The arrival of plague to European harbors was not followed by penetration into or establishment on the continent, possibly because rodents in Europe had become immunized by *Y. pseudotuberculosis* and subsequently resistant to plague (Mollaret, 1995). The same phenomenon was also observed in Japan. The first plague victim was identified in a steamship coming from Hong Kong to Nagasaki in 1890. Later, the disease reached harbors in Tokyo, Yokohama, Osaka, and Kobe and was prevalent among 2905 persons and 24,528

rats in Japanese harbors from 1899 to 1926 (Morita, 1995), but the plague did not penetrate into or become established in Japan, where *Y. pseudotuberculosis* might have been prevalent among wild animals from the Ice Age (Fukushima et al., 1998b). Human infection with *Y. pseudotuberculosis* in Japan was first reported in 1909 (Saisawa, 1913).

Yersinia pseudotuberculosis serotypes O:1a and 1b of the YPM⁻/HPI⁺ group and serotype O:3 of the YPMc⁺/R-HPI⁺ group spread to new continents, where enteropathogenic yersiniae are rare, following European emigrations since the eighteenth century (Slee and Skilbeck, 1992; Mollaret, 1995). Serotype O:3 strains (YPMc⁺/R-HPI⁺ group) were transported to the Far East by the import of pigs and their products from Western pig-producing countries since 1970s, and the same is true for *Y. enterocolitica* (Fukushima et al., 1997; Fig. 10).

Fig. 29. Monthly distribution of *Y. pseudotuberculosis* in humans and other animals in Britain 1961–1971. From Mair (1973).

Fig. 31. Relationship between breeding season and the incidence of *Y. pseudotuberculosis* in *A. speciosus*. From Fukushima et al. (1990a).

Fig. 30. Monthly distribution of *Y. pseudotuberculosis* in patients, animals and water in Shimane, Japan. From Fukushima et al. (1985c).

An effective and solid barrier against the spread of certain species or serotypes of *Yersinia* by some predominant types of *Yersinia* among domestic and wild animals is suggested by the following observations.

In China In Haiyuan county of the Ganning loess plateau plague focus, central China, where the main reservoir of *Y. pestis* is Mongolian ground squirrel living in farmlands and prairies, *Y. enterocolitica* O:9 is prevalent among pigs, dogs, hares and small rodents in and around a residential area but rarely among Mongolian ground squirrels (Fukushima et al., 2001a). The prevalence of *Y. pseudotuberculosis* is, however, rare among animals in this area. In Southern China, Guangxi and Shanghai, *Y. pseudotuberculosis* serotype O:1b, 1c, 2a, 2b, 3, 4b, 5b and 6 strains are prevalent among rabbits, house rats, and wild rats (Zheng et al., 1995) and *Y. enterocolitica* biotype 3/serotype O:3 strains are prevalent among pigs, rabbits, and house rats (Zheng, 1987; Zheng and Xie, 1996). These findings suggest the mosaic distribution of *Y. pestis* and two closely related species, *Y. pseudotuberculosis* and *Y. enterocolitica*, among wild and domestic animals in mainland China.

In Brazil *Yersinia pseudotuberculosis* is frequently distributed among domestic animals such as cattle, buffalos and pigs in the *Y. pestis* free areas, but never distributed in natural plague foci (D. P. Falcao, personal communication).

In Japan In western Japan where many cases of human *Y. pseudotuberculosis* infections have been reported, *Y. pseudotuberculosis* is frequently found in wild and domestic animals and in natural water, but pathogenic *Y. enterocolitica* are never isolated. Furthermore, although the most predominant serotype of clinical and animal isolates in Okayama (Sato, 1987b) and Shimane Prefectures (Fukushima et al., 1985b) was serotype O4b, the next four predominant serotypes differed between both areas (Fig. 22). Serotype O:2b, 5a and 5b strains are frequently found in humans and wild animals in Okayama (Inoue et al., 1991) but are rare in Shimane. In contrast, serotype O:1b strains are frequently found in humans and wild animals in Shimane (Fukushima and Gomyoda, 1991b) but rare in Okayama. This phenomenon was strengthened by the analysis of the REAP types of *Y. pseudotuberculosis* in a limited area (Fukushima et al., 1991c; Fukushima and Gomyoda, 1995b; Fig. 32). In Shimane Prefecture, almost all isolates from

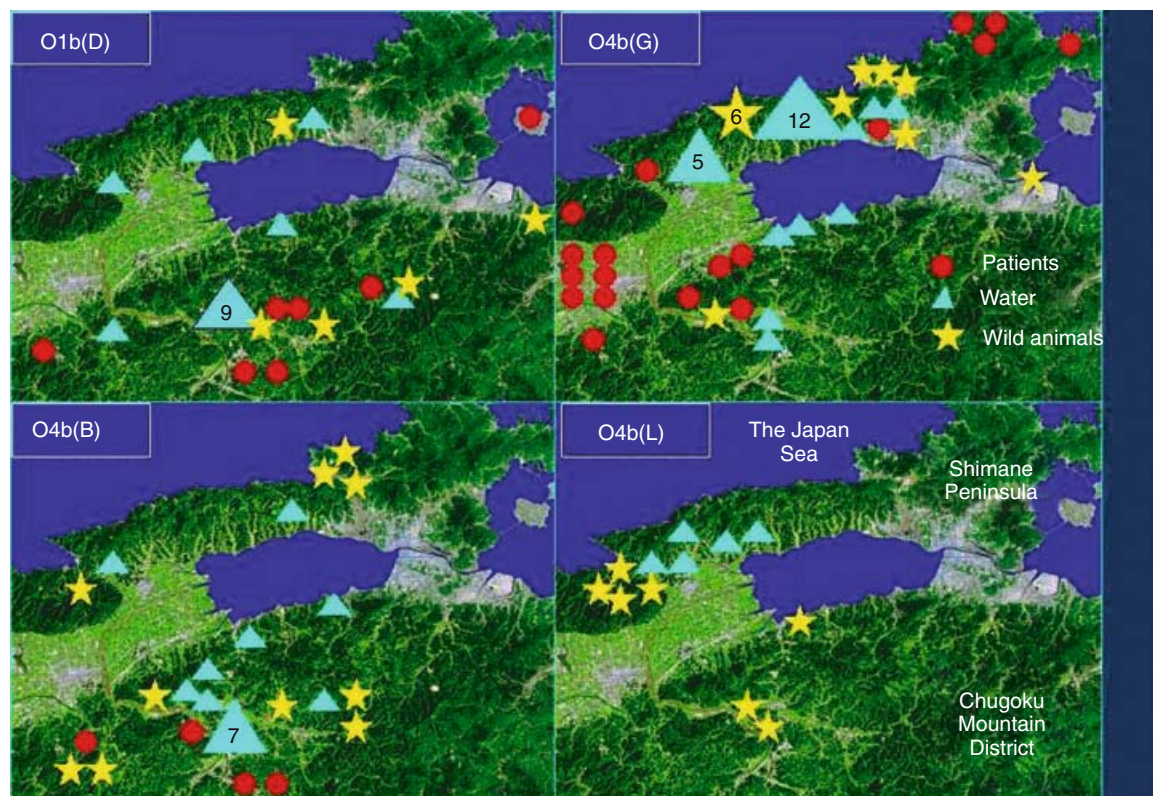

Fig. 32. Regional distribution of REAP patterns of *Y. pseudotuberculosis* serotypes O:1b and 4b among wild animals, in river water and humans in eastern Shimane prefecture.

Fig. 33. Pigs are viable carriers of *Y. enterocolitica* serotype O:3 only during primary infection. From Fukushima et al. (1984a).

humans and wild animals belonged to serotype O:1b and REAP pattern D (O:1b/D) and serotype O:4b/B, G, L, with the most predominant type being O:4b/G. The majority of serotype O:1b/D strains was prevalent among humans and wild animals in a limited area of Chugoku Mountain district of Japan. In much the same area with serotype O:1b/D strains, serotype O:4b/B strains were prevalent. Serotype O:4b/G strains were prevalent in Shimane Peninsula, while west of this area, strains of serotypes O:1b/D and O:4b/B were prevalent. Thus, serotype O:4b/G, widespread among wild animals in the examined area, seems to act as an effective barrier against other types of *Y. pseudotuberculosis*.

In eastern Japan, human and wild small rodent *Y. pseudotuberculosis* infections are rare (Saitoh et al., 1994; Hayashidani et al., 1995), while *Y. enterocolitica* serotype O:8 infection of wild rodents (2.2–5.2%; Iinuma et al., 1992; Hayashidani et al., 1995) and zoo animals (Sasaki et al., 1989) is common. In the Tsugaru region of Aomori Prefecture, where *Y. enterocolitica* serotype O:8 is highly prevalent in wild rodents in mountainous areas and cause sporadic human infections (Ichinohe et al., 1991; Saitoh et al., 1994), *Y. pseudotuberculosis* is infrequently found in wild animals (Hayashidani et al., 1995).

In the investigation of *Yersinia* in 1200 slaughtered pigs from 96 pig farms in Shimane Prefecture (Fukushima et al., 1989b; Fukushima et al., 1990b), pigs on 15 (6.4%) and 6 (1.6%) farms were found infected with *Y. enterocolitica* serotype O:3 and *Y. pseudotuberculosis* serotypes O:1b, 3, or 4b, respectively (Table 27). With the exception of the pig infections on two farms, pig infections were due either to *Y. pseudotuberculosis* or to *Y. enterocolitica* but never to both bacteria in each farm. The period of primary

infection is the only time when pigs are carriers of viable *Yersinia* (Fukushima et al., 1984a; Fig. 33).

In two remote mountainous villages of Okayama Prefecture (Inoue et al., 1988), two community infections with *Y. pseudotuberculosis* prevailed among residents who drank unchlorinated well water or mountain stream water (Fig. 34). This infection affected 173 of 245 children (70.6%) and 87 of 1157 adult residents (7.5%) in one outbreak, and 11 of 17 children (64.7%) in another outbreak, in which adult residents were not affected.

CONCLUSION *Yersinia pseudotuberculosis* has a wide distribution in most countries with cold climates and has been recognized as an important causal agent of sporadic and epidemic human enteric disease (Mair, 1965; Tsubokura et al., 1989). An interesting feature of the occurrence of *Y. pseudotuberculosis* infections in Japan, as compared to that in Western countries, is that 94 outbreaks involving 4741 patients throughout Japan from 1927 to 1950, and Kawasaki syndrome have occurred among children up until the 1990s (Fukushima et al., 1985b; Sato, 1987a; Tsubokura et al., 1989; Toyokawa et al., 1993). Almost all cases of *Y. pseudotuberculosis* infections in Japan occurred in mountainous areas, where residents drank natural unchlorinated water contaminated by *Y. pseudotuberculosis*-infected wild animals. Recently, waterworks and a decrease in child population in remote mountainous areas of Japan led to a gradual reduction in the importance of this bacterium in human infections. Therefore, the epidemiological importance of *Y. pseudotuberculosis* will decrease and will be replaced by its importance for plague control, since the enteropathogenic yersiniae,

Fig. 34. Two outbreaks in villages in Okayama Prefecture. From Inoue et al. (1988).

which are widespread among mammalian populations in various parts of the world, might serve as an efficient barrier against *Y. pestis* spread from natural foci (Alonso et al., 1980).

Clinical Manifestations of *Y. pseudotuberculosis* Infections (Mikael Prentice)

GASTROINTESTINAL ILLNESS *Yersinia pseudotuberculosis* causes mesenteric adenitis and chronic diarrhea in a wide variety of animals and birds on all continents (Mair, 1965; Martins et al., 1998). Outbreaks are noted in zoo animals (Bielli et al., 1999) and farmed deer (Sanford, 1995). Infection usually resolves spontaneously, but in stressful conditions in young animals, may progress to a fatal septicemia with widespread deposition of caseating lesions in lymphatic tissue (Sanford, 1995). In humans, the usual presentation includes fever and abdominal pain followed by diarrhea and vomiting (Knapp, 1958; Van Noyen et al., 1995). As with *Y. enterocolitica*, central abdominal and right iliac fossa pain that may simulate appendicitis (pseudoappendicitis) occurs (Weber et al., 1970; El-Maraghi and Mair, 1979; Attwood et al., 1987). At laparotomy, the usual finding is mesenteric adenitis without appendicitis and occasionally inflammation of the terminal ileum and cecum (Weber et al., 1970; Attwood et al., 1987; Physiopathology). In some infected children, enlargement of mesen-

teric lymph nodes sufficient to create an abdominal mass may be seen (Jelloul et al., 1997) and intussusception can occur (Koo et al., 1996a). Occasionally, *Y. pseudotuberculosis* has been isolated from an inflamed appendix (true appendicitis; Tsubokura et al., 1973; Grant et al., 1994) and has been associated with the rare chronic syndrome of granulomatous appendicitis (Lamps et al., 2001).

Histology of affected nodes shows granulomas with central necrosis and microabscess formation (Weber et al., 1970; El-Maraghi and Mair, 1979), and the organism can be recovered from mesenteric node culture (Weber et al., 1970; El-Maraghi and Mair, 1979). Isolation from feces is much less common than for *Y. enterocolitica* (Mair, 1965; Mair and Fox, 1986; Van Noyen et al., 1995), possibly because of poor growth on enteric media on primary isolation (Mair and Fox, 1986) and in most cases diagnosis is by serology (Mair and Fox, 1986; Attwood et al., 1987).

SYSTEMIC DISEASE *Septicemia* As for *Y. enterocolitica*, *Y. pseudotuberculosis* septicemia often affects patients with a pre-existing condition such as diabetes or a condition involving iron overload and/or liver disease (Mollaret et al., 1964; Marlon et al., 1971) including hemochromatosis (Conway et al., 1989), sickle cell disease (Bradley and Skinner, 1974), thalassemia (Gordts et al., 1984) or chronic hemodialysis (Boelaert et al., 1987). Unlike mesenteric aden-

itis, septicemia presentation is associated with a high mortality (Knapp, 1958; Macaulay et al., 1967; Borowski et al., 1971; Marlon et al., 1971; Ljungberg et al., 1995). In one case report of a patient with adult onset diabetes mellitus and *Y. pseudotuberculosis* septicemia, death occurred despite low levels of circulating endotoxin and cytokines normally associated with serious Gram-negative sepsis (Valtonen et al., 1995). Unlike *Y. enterocolitica*, *Y. pseudotuberculosis* septicemia associated with transfusion of stored blood has not been reported.

Mucocutaneous Syndromes *Yersinia pseudotuberculosis* has been implicated in the etiology of two childhood systemic syndromes: Izumi fever, first seen after the Second World War in Japan (Sato et al., 1983), and a similar syndrome first described in Vladivostok in 1959 termed "Far Eastern Scarletiform Fever" (Kuznetsov, 1974). These involved fever, rash, diarrhea, skin desquamation, strawberry tongue, vomiting, red and cracked lips, abdominal pain, arthralgias, and conjunctivitis. There is a case report of a similar illness in the child of an American serviceman in Korea (Krober et al., 1983). These symptoms and signs overlap with Kawasaki disease (Chiba et al., 1983; Sato et al., 1983), an acute febrile illness in infants and children worldwide carrying a 20% risk of developing coronary artery aneurysms (American Heart Association, 2001). *Yersinia pseudotuberculosis* infection has been described in one case report of Kawasaki disease in Japan (Konishi et al., 1997) and Kawasaki disease criteria have been found in cases of *Y. pseudotuberculosis* infection in Japanese children (Baba et al., 1991). The cause of Kawasaki disease is unknown but an immunological process involving bacterial superantigens has been suggested (Yarwood et al., 2000; Superantigens of *Y. pseudotuberculosis*). Superantigen (*Y. pseudotuberculosis*-derived mitogen, YPM) production occurs in *Y. pseudotuberculosis* infection (Abe et al., 1997b), but there is no evidence linking *Y. pseudotuberculosis* with most clinical cases of Kawasaki disease (Yanagawa, 1989; Uchiyama and Kato, 1999).

POST-INFECTIVE PHENOMENA *Yersinia pseudotuberculosis* infection is a significant cause of childhood interstitial nephritis in Japan (Iijima et al., 1989; Kobayashi et al., 2000) and Korea (Koo et al., 1996b). However, this syndrome of acute tubulointerstitial nephritis (interstitial edema with inflammatory cell infiltrates and tubular damage) is a rarer cause of childhood renal failure than glomerulonephritis even in these countries (Kobayashi et al., 2000). There is a report of *Y. pseudotuberculosis* infection and nephritis in an adult in Finland (Tertti et al., 1984). Hemolytic

uremic syndrome has been reported in association with *Y. pseudotuberculosis* infection in two adults in the United Kingdom (Davenport et al., 1987; Davenport and Finn, 1988) and a child in California (Prober et al., 1979).

The other main postinfective complication of *Y. pseudotuberculosis* infection is arthritis (Yli-Kerttula et al., 1995; Clinical manifestations of *Y. enterocolitica* and Immunology). In one patient, this has been associated with persistence of bacterial antigens and *Y. pseudotuberculosis* 16S rRNA detectable by reverse transcriptase-polymerase chain reaction (RT-PCR) in affected joints over several years (Gaston et al., 1999). HLA-B27-negative individuals are subject to reactive arthritis following *Y. pseudotuberculosis* infection (Tertti et al., 1984) but seem less likely to develop ankylosing spondylitis than HLA B27-positive individuals (Yli-Kerttula et al., 1995). In the long term (over 10 years), arthritis may persist despite the disappearance of detectable circulating anti-*Y. pseudotuberculosis* antibodies (Yli-Kerttula et al., 1995). The numbers of individuals suffering reactive arthritis may depend on the infecting strain (Tertti et al., 1989; Yli-Kerttula et al., 1995). As for reactive arthritis following infection with *Y. enterocolitica* and other bacteria, erythema nodosum, uveitis and keratoderma often occur as part of the presentation of *Y. pseudotuberculosis*-associated reactive arthritis (Tertti et al., 1984; Tertti et al., 1989; Yli-Kerttula et al., 1995).

Bacteriological Diagnosis of *Y. pseudotuberculosis* (Georges Wauters)

Yersinia pseudotuberculosis is able to grow on most selective media used for *Y. enterocolitica* (Bacteriological diagnosis of *Y. enterocolitica*) but its growth is often poor and delayed. Cold enrichment is suitable as for *Y. enterocolitica*.

Yersinia pseudotuberculosis can be differentiated from *Y. pestis* by motility and the presence of urease, from *Y. enterocolitica* by the lack of ornithine-decarboxylase, by acid production from rhamnose and usually melibiose, but not from sucrose and cellobiose (Table 1).

Thirty somatic antigens and five H antigens have been described in *Y. pseudotuberculosis* but a simplified antigenic scheme containing 14 serogroups has been proposed by Tsubokura and Aleksic (Tsubokura and Aleksic, 1995; Epidemiology of *Y. pseudotuberculosis*).

Pathogenesis

One critical element for the expression of a pathogenicity phenotype in *Yersinia* is the presence of the virulence plasmid (pYV). Without

this replicon, yersiniae are avirulent. In addition, the subgroup of highly pathogenic strains possesses a chromosomal entity, the high pathogenicity island (HPI), which is required for their systemic dissemination in the host. These two large genetic elements, although crucial for the development of disease (mild or severe), are necessary but not sufficient to cause an infection. Many other factors, including invasins, toxins, and adhesins, participate in the pathogenic potential of yersiniae. The best-characterized, confirmed or putative, virulence factors of enteropathogenic *Yersinia* are described in this chapter.

The pYV Virulence Plasmid (Guy Cornelis)

DEVICES TO INJECT BACTERIAL PROTEINS ACROSS EUKARYOTIC CELL MEMBRANES

A Plasmid Determining Virulence The three pathogenic *Yersinia* species (*Y. pestis*, *Y. pseudotuberculosis* and *Y. enterocolitica*) are known since the early 1960s to be dependent on Ca^{2+} for their growth at 37°C. Variants that lost this requirement appear spontaneously when wild-type bacteria are plated at 37°C in the absence of Ca^{2+} . These variants, called “ Ca^{2+} -independent” have lost their virulence (Higushi and Smith, 1961). This Ca^{2+} -dependency phenotype offered an extraordinary clue to the pathogenicity arsenal because nonvirulent mutants could be easily detected and even selected for. In 1980, it appeared that both virulence and Ca^{2+} -dependency were encoded by a 70-kb plasmid (Zink et al., 1980; Gemski et al., 1980; Portnoy and Falkow, 1981a). Under conditions of growth restriction, it then appeared that this plasmid governs the synthesis of a set of about 12 proteins called “Yops” for “*Yersinia* outer membrane proteins” (Portnoy et al., 1981b; Straley and Brubaker, 1981; Bölin et al., 1982; Martinez, 1983; Cornelis et al., 1986; Forsberg et al., 1987). The LcrV protein, an antigen of *Y. pestis*, discovered in the mid 1950s (Burrows and Bacon, 1956), turned out to be one of these Yops (Straley and Brubaker, 1981). Although initially described as outer membrane proteins, the Yops could also be recovered from the culture supernatant (Heesemann et al., 1984), and they turned out later to be actually secreted proteins (Michiels et al., 1990). Their secretion appeared to occur by a new pathway (now called “type III”) and to require a specific apparatus of a new type, now called the “Ysc apparatus,” which is also encoded by the pYV plasmid (Michiels et al., 1991).

The Yersinia Ysc Secretion Apparatus “Yop secretion” was discovered around 1990 while trying to understand the mysterious phenomenon of Ca^{2+} -dependency: when incubated at 37°C in the

absence of Ca^{2+} , *Yersinia* bacteria do not grow, but instead, release large amounts of proteins called Yops in the culture supernatant (Michiels et al., 1990). Although it is generally referred to as Yop “secretion,” it is not a physiological secretion but rather a massive leakage resulting from the artificial opening of an otherwise tightly controlled delivery apparatus. Despite that it is presumably artefactual, this observation turned out to be of paramount importance because it allowed the characterization of the Ysc (for Yop secretion) secretion apparatus, an archetype for the type III secretion systems. The Ysc apparatus, also referred to as the “Ysc injectisome” (see below), has 29 Ysc proteins. Ten of these Ysc proteins (YscD, -J, -L, -N, -Q, -R, -S, -T, -U and -V) have counterparts in almost every type III secretion apparatus as well as in the flagellum. Their homologues in the flagellum are localized in the MS ring and the C ring, which constitute the inner part of the basal body (Minamino and Macnab, 1999). In good agreement with this finding, YscD, -R, -U and -V, (formerly called “LcrD”) have been shown and YscS and -T have been predicted to span the inner membrane. YscN has ATP-binding motifs (Walker boxes A and B) resembling the b catalytic subunit of the F₀F₁ proton translocase and related ATPases (Woestyn et al., 1994). Also, YscN is part of a complex including also YscL, YscK and YscQ (Jackson and Plano, 2000). YscJ is a lipoprotein that has not been localized yet, but its counterpart in *P. syringae* has been shown to span the inner and the outer membranes (Deng and Huang, 1999). Thus, the ten conserved proteins constitute the proximal part of the injectisome, spanning or attached to the inner membrane.

YscC also has counterparts in every type III secretion system but not in the flagellum. It belongs to the family of secretins, a group of outer-membrane proteins involved in the transport of various macromolecules and filamentous phages across the outer membrane. As do the other secretins, it forms a ring-shaped structure with an external diameter of about 200 Å and an apparent central pore of about 50 Å (Koster et al., 1997). At least one disulfide bond is essential for its assembly (Jackson and Plano, 1999), and its proper insertion in the outer membrane requires the presence of an ancillary lipoprotein called “YscW” (Koster et al., 1997).

Some Ysc proteins including YscO, -P and -X are released by Ca^{2+} -chelation together with the substrates of the Ysc apparatus. They are nevertheless required for Yop secretion and hence must constitute the most external part of the injectisome (Payne and Straley, 1998a; Payne and Straley, 1999; Iriarte and Cornelis, 1999a; Day and Plano, 2000a; Stainier et al., 2000). The fact that some of the Ysc proteins are themselves

secreted upon Ca^{2+} -chelation suggests that some of the Yop proteins could also be proteins of the injectisome structure rather than substrates as anticipated. This could be the case of YopN. Indeed, it is encoded in the same locus as *yscX* and it is required to prevent a deregulated secretion of Yops (Forsberg et al., 1991).

According to electron microscopy observations, the Ysc injectisome ends up with a needle formed by polymerization of the 6-kDa YscF (Hoiczky and Blobel, 2001). Isolated needles have a length of 600–800 Å and a width of 60–70 Å. The needle has a hollow center of about 20 Å.

Little is known about the actual mechanism of export, but it is generally assumed that the Ysc apparatus serves as a hollow conduit through which the exported proteins travel to cross the two membranes and the peptidoglycan barrier in one step. Whether proteins travel folded or unfolded has not yet been demonstrated, but given the size of channel, it is likely that they travel, at least partially, unfolded.

Translocation of Effectors Across Eukaryotic Cell Membranes Purified secreted Yops have no cytotoxic effect on cultured cells, although live extracellular *Yersinia* have such an activity. Cytotoxicity was nevertheless found to depend on the capacity of the bacterium to secrete YopE and YopD. However, YopE alone was found to be cytotoxic when microinjected into the cells. This observation led to the hypothesis that YopE is a cytotoxin that needs to be injected into the eukaryotic cell's cytosol by a mechanism involving YopD to exert its effect (Rosqvist et al., 1991). In 1994, this hypothesis was demonstrated by two different approaches. The group of Hans Wolf-Watz used immunofluorescence and confocal laser scanning microscopy examinations (Rosqvist et al., 1994), while the group of Guy Cornelis introduced a reporter enzyme strategy based on the calmodulin-activated adenylate cyclase (Sory and Cornelis, 1994). Infection of a monolayer of eukaryotic cells by a recombinant *Y. enterocolitica* producing a hybrid protein made of the N-terminus of YopE and the catalytic domain of the adenylate cyclase of *Bordetella pertussis* (YopE-Cya protein) led to an accumulation of cyclic AMP in the cells. Since the cyclase is not functional in the bacterial cell and in the culture medium because of a lack of calmodulin, this accumulation of cAMP signified the internalization of YopE-Cya into the cytosol of eukaryotic cells (Sory and Cornelis, 1994). Thus, extracellular *Yersinia* inject YopE into the cytosol of eukaryotic cells by a mechanism that involves at least one other Yop protein, YopD. That YopH was also injected into the target cell cytosol was later demonstrated (Persson et al., 1995; Sory et al., 1995), and the requirement of

YopB for delivery of YopE and YopH, like YopD was shown (Boland et al., 1996; Nordfelth and Wolf-Watz, 2001). These observations led to the present concept that Yops are a collection of intracellular effectors (including YopE and YopH) and proteins (including YopB and YopD) required for translocation of these effectors across the plasma membrane of eukaryotic cells (Cornelis and Wolf-Watz, 1997). Delivery of effector Yops into eukaryotic cells appears to be a directional phenomenon in the sense that the majority of the Yop effector molecules produced are directed into the cytosol of the eukaryotic cell and not to the outside environment (Rosqvist et al., 1994; Persson et al., 1995).

This model of intracellular delivery of Yop effectors by extracellular adhering bacteria is now largely supported by a number of other results, including immunological observations. While antigens processed in phagocytic vacuoles of phagocytes are cleaved and presented by major histocompatibility complex (MHC) class II molecules, epitope 249–257 of YopH produced by *Y. enterocolitica* during a mouse infection is presented by MHC class I molecules, like cytosolic proteins (Starnbach and Bevan, 1994).

A Pore Formed by Translocators The translocators YopB and YopD have hydrophobic domains suggesting that they could act as transmembrane proteins (Rosqvist et al., 1994; Sory and Cornelis, 1994; Persson et al., 1995; Boland et al., 1996). In agreement with this, *Yersinia* has a contact-dependent lytic activity on sheep erythrocytes, depending on YopB and YopD (Hakansson et al., 1996; Neyt and Cornelis, 1999a), which suggests that the translocation apparatus involves some kind of a pore in the target cell membrane by which the Yop effectors pass through to reach the cytosol. This YopB- and YopD-dependent lytic activity is higher when the effector *yop* genes are deleted, suggesting that the pore is normally filled with effectors (Hakansson et al., 1996; Neyt and Cornelis, 1999a). The idea of a translocation pore is further supported by the observation that the membrane of macrophage-like cells infected with an effector polymutant *Y. enterocolitica* becomes permeable to small dyes (Neyt and Cornelis, 1999a). If the macrophages are pre-loaded prior to the infection with a low-molecular weight fluorescent marker, they release the fluorescent marker but not cytosolic proteins, indicating that there is no membrane lysis but rather insertion of a small pore (diameter 16–23 Å) into the macrophage plasma membrane (Neyt and Cornelis, 1999a). The hypothesis of a channel is reinforced by the observation that artificial liposomes that have been incubated with *Yersinia* contain channels detectable by electrophysiology (Tardy et al.,

1999). All these events are dependent on the presence of the translocators YopB and YopD. These two hydrophobic Yops seem thus to be central for the translocation of the effectors and for the formation of a channel in lipid membranes. They presumably play different roles in pore formation. Indeed, YopB alone can disturb artificial membranes, while YopD cannot. Moreover, YopD has been shown to end up in the cytosol of eukaryotic cells (Francis and Wolf-Watz, 1998).

YopB and YopD are encoded by a large operon that also encodes LcrV, LcrG and the chaperone SycD. Also, LcrV is a secreted Yop that has a different name for historical reasons. The fact that LcrG and LcrV are encoded together with translocators suggests that they could also be involved in the translocation step. Not surprisingly, LcrV interacts with YopB and YopD (Sarker et al., 1998), is surface-exposed before target cell contact (Pettersson et al., 1999), and is indeed required for translocation (Sarker et al., 1998; Lee et al., 2000; Holmstrom et al., 2001). However, in addition to this role as a translocator, LcrV also plays a still not understood intrabacterial regulatory role in Yop synthesis (Nilles et al., 1998).

Unlike YopB, YopD and LcrV, LcrG is not a released protein but its exact localization in the bacterium remains elusive. It is required for efficient translocation of *Yersinia* Yop effector proteins into the eukaryotic cells, but it is not required for pore formation. It binds to LcrV. Like LcrV and presumably through its interaction with LcrV, it also plays a regulatory role (Lee et al., 2000). LcrG has also been shown to bind heparin sulfate proteoglycans (Boyd et al., 1998) but the significance of this binding is not clear.

The fact that LcrV, YopB and YopD are involved in translocation of the effector Yops does not necessarily exclude that some of them could themselves end up in the eukaryotic cytoplasm, as was shown for YopD and LcrV (Francis and Wolf-Watz, 1998; Fields and Straley, 1999).

It is not known yet whether the translocators are already present at the tip of the “needle” prior to contact with a eukaryotic cell or whether they are the first proteins to be secreted upon contact with a target cell.

The Cytosolic Chaperones A hallmark of type III secretion is that normal secretion of some substrate proteins requires the presence of small cytosolic chaperones of a new type (Menard et al., 1994; Wattiau et al., 1994b; Wattiau et al., 1996). Generally, these chaperones are encoded by genes proximal to the gene encoding the protein they serve, and this is a useful way to recognize such chaperones. However, in *Y. pseudotuberculosis*, the gene encoding the chap-

erone of YopH was separated from the *yopH* gene by a large inversion. SycE, the chaperone of YopE is the archetype of a first family of “type III chaperones” (Wattiau and Cornelis, 1993). There are four typical representatives of this family in *Yersinia*: SycE, SycH, SycT and SycN. One could also add to this list the less typical YscB, acting as a co-chaperone for YopN (Day and Plano, 1998; Jackson et al., 1998). All these chaperones are small (14–15 kDa) proteins with a putative C-terminal amphiphilic α -helix, and most of them are acidic (pI 4.4–5.2). They specifically bind only to their partner Yop, and in their absence, secretion of the cognate protein is severely reduced, if not abolished. However, the exact role of these chaperones remains elusive. Both SycE and SycH bind to their partner Yop at a unique site spanning roughly residues 20 to 70 (Sory et al., 1995). Surprisingly, when this site is removed, the cognate Yop is still secreted—though maybe in reduced amounts—and the chaperone becomes dispensable for secretion (Woestyn et al., 1996). This suggests that it is the binding site itself that creates the need for the chaperone and thus the chaperone somehow protects this site from premature associations, which would lead to degradation. In agreement with this hypothesis, SycE has indeed an anti-degradation role: the half-life of YopE is longer in wildtype bacteria than in *sycE* mutant bacteria (Frithz-Lindsten et al., 1995; Cheng et al., 1997). In addition to having this putative role of body-guard, SycE also acts as a secretion pilot leading the YopE protein to the secretion locus (see below). Finally, both SycE and SycH are required for efficient translocation of their partner Yop into eukaryotic cells (Sory et al., 1995). However, when YopE is delivered by a *Yersinia* polymutant strain that synthesizes an intact secretion and translocation apparatus but no other effector, it appears that YopE is delivered without the chaperone and the chaperone-binding site (Boyd et al., 2000). Thus, the SycE chaperone appears to be needed only when YopE competes with other Yops for delivery. This suggests that the Syc chaperones could be involved in some kind of a hierarchy for delivery. This new hypothesis about the role of the Syc chaperones fits quite well with the observation that only a subset of the effectors seem to have a chaperone. Little is known about the role of SycT and SycN. However, there is an unexpected complexity for the latter: SycN apparently requires YscB working as a co-chaperone (Day and Plano, 1998).

SycD is the archetype of a second group of “type III chaperones.” It serves the translocators YopB and YopD (Wattiau et al., 1994b; Neyt and Cornelis, 1999b), and in its absence, YopD and YopB are less detectable inside the bacterial cell.

SycD appears to be different from SycE and SycH in the sense that it binds to several domains on YopB (which evokes rather SecB, a molecular chaperone in *E. coli* dedicated to the export of newly synthesized proteins) and also has multiple binding sites on its targets (Fekkes and Driesen, 1999). IpgC, the related chaperone from *S. flexneri*, has been shown to prevent the intrabacterial association between translocators IpaB and IpaC (Menard et al., 1994). The similarity between IpgC and SycD suggested that SycD could play a similar role and would thus prevent the intrabacterial association of YopB and YopD. However Neyt and Cornelis (1999b) observed that intrabacterial YopB and YopD are associated in the bacterium, even in the presence of SycD. Since YopB and YopD have also the capacity to bind to LcrV, one could speculate that SycD prevents a premature association, not between YopB and YopD but rather between YopB, YopD and LcrV. However, this has not been shown yet.

Finally, it appears that some external components of the injectisome itself have a chaperone. YscG has been suggested to be the chaperone of YscE (Day et al., 2000b) and YscY could be the chaperone of YscX (Day and Plano, 2000a). The role of these chaperones could be to prevent intrabacterial association of the distal components of the injectisome.

Recognition of the Transported Proteins Effectors delivered by the type III secretion systems have no classical cleaved N-terminal signal sequence (Michiels et al., 1990). However, it is very clear that Yops are recognized by their N-terminus but that no classical signal sequence is cleaved off during Yop secretion (Michiels et al., 1990). The minimal region shown to be sufficient for secretion was gradually reduced to 17 residues of YopH (Sory et al., 1995), to 15 residues of YopE (Sory et al., 1995), and to 15 residues of YopN (Anderson and Schneewind, 1997).

The secretion domains of the Yops are not similar, suggesting recognition of a conformational motif of the nascent protein (Michiels et al., 1990). To explain how the same secretion apparatus could recruit proteins with no common signal (Wattiau and Cornelis, 1993), it was suggested that the Syc chaperones could serve as pilots. However, this hypothesis was questioned when it appeared that YopE could be secreted even if its chaperone-binding domain had been deleted (Woestyn et al., 1996). It was then concluded that secretion was only dependent on the short N-terminal signal, but secretion of a Yop lacking only this N-terminal signal had never been tested.

A systematic mutagenesis of the secretion signal by Anderson and Schneewind (Anderson

and Schneewind, 1997; Anderson and Schneewind, 1999) led to doubts about the proteic nature of this signal. No point mutation could be identified that specifically abolished secretion of YopE, YopN and YopQ. Moreover, some frame-shift mutations that completely altered the peptide sequences of the YopE and YopN signals also failed to prevent secretion. Anderson and Schneewind (Anderson and Schneewind, 1997; Anderson and Schneewind, 1999) concluded from these observations that the signal that leads to the secretion of these Yops could be in the 5'-end of the messenger RNA, rather than in the peptide sequence. Translation of *yop* mRNA might be inhibited by either its own RNA structure or as a result of its binding to other regulatory elements. However, this mRNA signal hypothesis is contradicted by recent work of Lloyd and colleagues (Lloyd et al., 2001). These authors show that mutations of the first 11 codons of YopE, modifying the mRNA but not the amino acid sequence, do not impair secretion, suggesting that it is the N-terminus of YopE and not the 5' end of *yopE* mRNA that serves as a targeting signal.

To determine whether this N-terminal (or 5'-terminal) signal is absolutely required for YopE secretion, Cheng et al. (1997) deleted codons 2–15 and they observed that 10% of the hybrid proteins deprived of the N-terminal secretion signal were still secreted. They inferred that there is a second secretion signal, and they showed that this second, and weaker, secretion signal corresponds to the SycE-binding site. Not surprisingly, this secretion signal is only functional in the presence of the SycE chaperone (Cheng et al., 1997), rejuvenating the pilot hypothesis of Wattiau and Cornelis (1993). The Syc chaperone could ensure stability and proper conformation of the protein and target it to the secretion channel. At the moment of secretion, the chaperone must be released from the partner Yop to allow secretion.

Thus, the effectors that have a chaperone, like YopE, YopH, YopN and YopT, are likely to have two secretion signals that operate during *in vitro* secretion: one linked to translation and one, post-translational. What is the relative importance of these two systems *in vivo* remains to be elucidated.

Control of the Injection We have seen that “type III secretons” can secrete their substrate *in vitro* under given conditions, such as Ca^{2+} -chelation for instance. What is the triggering signal *in vivo*? Most probably, it is contact with a eukaryotic cell. Several reports on *Yersinia* have shown that Yops delivery is a “directional” phenomenon in the sense that most of the load is delivered inside the eukaryotic cell and that there is little leakage

(Persson et al., 1995). With the assays used, measurement of the degree of "directionality" is somewhat discrepant (Boland et al., 1996), but there is no doubt that the majority of the released Yops load ends up within the eukaryotic cell and thus that contact must be the signal. Pettersson et al. (1996) provided a nice visual demonstration of the phenomenon. By expressing luciferase under the control of a *yop* promoter, they showed indeed that active transcription of *yop* genes is limited to bacteria that are in close contact with eukaryotic cells.

EFFECTOR PROTEINS AND HOST RESPONSES *The Cytoskeleton is a Target of YopE, YopH, YopT and YpkA (YopO)* Four effectors, out of six identified so far, exert a negative role on the cytoskeleton dynamics, and by doing so, contribute to the strong resistance of *Yersinia* to phagocytosis by macrophages (Rosqvist et al., 1991; Grosdent and G. R. Cornelis, unpublished observation). YopH is a powerful phosphotyrosine phosphatase resembling eukaryotic phosphatases. The catalytic activity is exerted by the C-terminal domain (residues 206–408), which contains a phosphate-binding loop including a critical cysteine residue (cys 403; Guan and Dixon, 1993). In HeLa cells, YopH dephosphorylates p130^{Cas}, paxillin and the focal adhesion kinase (FAK; Black and Bliska, 1997; Persson et al., 1997; Black et al., 1998), which leads to disruption of the focal adhesion and a reduced invasion-mediated engulfment. YopH is specifically targeted to the focal complexes and residues 223–226, known to be surface-exposed and involved in this process. Deletion of these targeting residues affects the antiphagocytic effect. These observations also apply to the J774 macrophage-monocyte cell line, at least in the absence of opsonization (Persson et al., 1999). In the latter cell line, a catalytically inactive YopH co-precipitates not only with p130^{Cas} but also with the Fyn-binding protein FYB (Hamid et al., 1999) and the SKAP-HOM protein (Black et al., 2000). The N-terminal domain of YopH binds not only to SycH (Sory et al., 1995) but also the substrate (Montagna et al., 2001). Yao et al. (1999) observed that T and B cells transiently exposed to *Yersinia* are impaired in their ability to be activated through their antigen receptors. The T cells are inhibited in their ability to produce cytokines, and B cells are unable to upregulate surface expression of the costimulatory molecule B7.2, in response to antigenic stimulation. This block of activation results from the inhibition of early phosphorylation events (Yao et al., 1999). Through the analysis of various mutants, YopH appeared to be the main effector involved in these events. Thus YopH not only contributes to the evasion of the innate immune response by inhib-

iting phagocytosis but it can also incapacitate the host adaptive immune response.

YopE has been known for a long time to disrupt actin filaments (Rosqvist et al., 1990; Rosqvist et al., 1991). In vitro, it acts as a GTPase-activating protein (GAP) for monomeric GTPases of the Rho family controlling the cytoskeleton dynamics (von Pawel-Rammingen et al., 2000). YopE has an arginine finger motif similar to those found in other GAP proteins. Exchange of arginine 144 from this motif results in loss of the GAP activity and inability to induce cytotoxicity on cultured HeLa cells (von Pawel-Rammingen et al., 2000). Experiments conducted in human umbilical vein endothelial cells (HUVECs) show that YopE can inhibit Rac- but not Rho- or Cdc42-regulated actin structures, and more specifically, that YopE is capable of blocking Cdc42-dependent Pac activation but not direct Pac activation (Andor et al., 2001). This GAP activity of YopE has been shown to be a key of the antiphagocytic function of YopE (Black et al., 2000).

YopT exerts its depolymerizing effect on actin (Iriarte and Cornelis, 1998) by modifying RhoA, a GTPase that regulates the formation of stress fibers (Zumbihl et al., 1999). The exact nature of the modification is still unknown.

YpkA (YopO) also leads to a morphological alteration of the target cells due to the disruption of the actin cytoskeleton. A serine-threonine kinase, YpkA, shows some similarity with eukaryotic serine/threonine protein kinases (Galyov et al., 1993) and becomes activated by interacting with actin through the C-terminal twenty amino acids of YpkA (Juris et al., 2000). The amino terminus contains the kinase domain, while the carboxy terminus interacts with RhoA and Rac-1, preferably bound to GDP (Barz et al., 2000; Dukuzumuremyi et al., 2000). Inside the HeLa cells, the YpkA protein is targeted to the inner surface of the plasma membrane (Hakansson et al., 1996).

YopP/YopJ Downregulates the Inflammatory Response YopP/YopJ is a key player in the downregulation of the inflammatory response that is observed during *Yersinia* infection. In vitro, YopP/YopJ has indeed been shown to counteract the normal proinflammatory response of various cell types. Its injection reduces the release of tumor necrosis factor (TNF- α , Boland and Cornelis, 1998a) by macrophages and of interleukin (IL-8) by epithelial (Schulte et al., 1996; Schesser et al., 1998) and endothelial cells (Töttemayer et al., 2002). It also reduces the presentation of adhesion molecules (intercellular adhesion molecule [ICAM-1] and E-selectin) at the surface of endothelial cells (Töttemayer et al., 2002) and hence presumably

reduces neutrophil recruitment to the infection sites. All these events result from the inhibition of the activation of nuclear factor (NF- κ B), a transcription factor known to be central in the onset of inflammation (Ruckdeschel et al., 1998; Schesser et al., 1998). The inhibition of NF- κ B activation was recently shown to result from the inhibition by YopP/YopJ of IKK β , a kinase that phosphorylates I κ B, the inhibitor of NF- κ B (Orth et al., 1999). By preventing phosphorylation of I κ B, YopP/YopJ prevents its degradation and the translocation of NF- κ B to the nucleus.

The inhibition of NF- κ B activation is accompanied by a lack of activation of the mitogen-activated protein (MAP) kinases (MAPK), c-jun-N-terminal kinase (JNK), p38, and extracellular signal-regulated kinase (ERK) 1 and 2 (Ruckdeschel et al., 1997; Boland and Cornelis, 1998a; Palmer et al., 1999) that is observed upon infection of macrophages by a *Yersinia* producing YopP/YopJ. This lack of activation of the MAPK results from the inhibition of the upstream MAPK kinases (MKK; Orth et al., 1999), but direct binding of YopP/YopJ to MKKs has not been documented. Inhibition of the MAPK pathways abrogates phosphorylation of cyclic AMP response element-binding (CREB) protein, another transcription factor involved in the immune response (Meijer et al., 2000).

Last but not least, YopP/YopJ induces apoptosis in macrophages but not in other cell types (Mills et al., 1997; Monack et al., 1997). This apoptosis is accompanied by cleavage of the cytosolic protein BID, the release of cytochrome c, and the cleavage of caspase-3, -7 and -9 (Denecker et al., 2001). The release of cytochrome c and the cleavage of BID can both be inhibited by caspase inhibitors, suggesting that YopP/J interferes with a signaling pathway upstream of the mitochondria (Zhang et al., 1997). However, this signaling pathway has not been identified yet, and one may wonder whether apoptosis does not result from the loss of the anti-apoptotic factor NF- κ B (Ruckdeschel et al., 1998; Ruckdeschel et al., 2001).

Starting from the observation that the predicted secondary structure of YopJ/P resembles that of an adenovirus protease, Orth et al. (2000) identified and mutated the critical cysteine and histidine of the putative protease catalytic site. They observed that mutations in this site affected the ability of YopJ/P to inhibit activation of the MAPK pathway, as determined by measuring extracellular ERK activity in response to treatment by the epidermal growth factor (EGF). Mutant YopJ/P has also lost the capacity to inhibit translocation of NF- κ B to the nucleus, as induced by overexpression of a constitutively active form of mitogen-activated protein/ERK kinase kinases (MEKK), in vitro (Orth et al.,

2000). A similar mutant, generated in *Y. enterocolitica* has lost the capacity to induce apoptosis of macrophages. Thus, an intact protease catalytic site is required for YopJ/P activity, suggesting that YopP could be a protease. Orth et al. (2000) pursued the protease hypothesis, discovering a limited sequence similarity between YopJ/P and the catalytic core of the yeast ubiquitin-like protease Ulp1 that cleaves the COOH-terminus of an 11-kDa small ubiquitin-related modifier (SUMO-1) protein. SUMO-1 is the best-characterized member of a rapidly growing family of ubiquitin-like proteins that are involved in posttranslational modification. To verify whether YopJ/P could act as a SUMO-protease, Orth et al. (2000) transfected cells with either wildtype or mutated forms of YopJ/P and SUMO-1. In their system, YopJ/P reduced the cellular concentration of SUMO-1-conjugated proteins as well as the amount of free SUMO-1, while cells transfected with mutant YopJ/P did not, suggesting that indeed YopJ/P acts as a SUMO-protease. This intriguing observation raises the question of consistency with the previous findings that YopJ/P interacts with the MKKs and IKK β pathways, preventing their phosphorylation. At first sight, the two observations may even appear to be contradictory. SUMO-1 is indeed supposed to protect I κ B α from phosphorylation. Thus, by de-SUMOylating I κ B α , YopJ/P should promote and not prevent its phosphorylation. To reconcile the two observations, Orth et al. (2000) propose that the MKKs or IKK β could activate and escort YopJ/P to the signaling complex, where it would silence critical SUMO-1 conjugated proteins. This would, in turn, prevent phosphorylation of MKKs and IKK β .

YopM YopM is a strongly acidic protein containing leucine-rich repeats (LRRs); although it clearly contributes to pathogenesis (Leung et al., 1990), its action and target remain unknown. It belongs to a growing family of type III effectors that has several representatives in *Shigella* (*ipaH* multigene family) and *Salmonella* (Miao et al., 1999). Early work has shown that YopM binds to thrombin suggesting that YopM could play a role as an extracellular virulence factor (Leung et al., 1990). However, delivery of YopM (like the other Yop effectors) into eukaryotic target cells has been shown (Boland et al., 1996). When inside cells, YopM has been shown to travel to the cell's nucleus by a vesicle-associated pathway (Skrzypek et al., 1998), but its action in the nucleus remains unknown.

Regulation of Transcription of the Virulon Genes Transcription of the *ysc* genes and the *yop* genes is thermoinduced. This thermoregulation results from the interplay between the tran-

appear to be more dispersed, suggesting that they were recruited more recently in the virulon. In pYVe227, the four chaperones SycE, SycH, SycD, and SycT are encoded next to their cognate gene. Gene *sycN* is separated from *yopN* by *tyeA*, but the latter also encodes a protein that interacts with YopN. Between *yopP* and *yopQ* lies the gene encoding the outer membrane lipoprotein YlpA (China et al., 1990). YlpA is highly homologous to the TraT proteins encoded by a number of bacterial plasmids.

In summary, a very compact group of 35 genes encoding the secretion-translocation apparatus is flanked on either side by the genes encoding the Yop effectors and their chaperones. All the genes encoding the virulon are thus clustered, as they would be on a pathogenicity island and virulence plasmid.

Interestingly, the gene encoding the adhesin YadA, which is essential for the Yop virulon in *Y. enterocolitica* but not in *Y. pseudotuberculosis* and *Y. pestis* is separated from the genes encoding the core of the apparatus, indicating that the adhesin may have been recruited more recently by the system (Balligand et al., 1985; Iriarte and Cornelis, 1999a).

The DNA composition of the genes encoding the type III secretion system in several bacteria differs from that of the genomic DNA of the corresponding bacteria. This is not the case here. The average G+C content of the genes encoding the Yop virulon in *Y. enterocolitica* is indeed 44.4% (Iriarte and Cornelis, 1999a), which is not very different from the reported G+C content of the *Y. enterocolitica* chromosome (46–50 mol%; Carniel et al., 1996). This observation suggests that these genes have been in Enterobacteriaceae, if not in *Yersinia*, for a long time.

Ancillary Functions: Replication and Partition System The replicon of the pYVe227 plasmid of *Y. enterocolitica* is of the RepFIIA type (archetype R100; Vanooteghem and Cornelis, 1990). The replication machinery consists of two proteins (the RepA replicase and the RepB regulator) and an origin of replication (*oriR*; Vanooteghem and Cornelis, 1990). The pYVe227 plasmid is incompatible with the sex factor F (Kalmykova et al., 1988) because they share a similar partition function (Biot and Cornelis, 1988). This function consists of two proteins, SpyA and SpyB, (for stability of pYV) encoded by an operon (Iriarte and Cornelis, 1999a). SpyA resembles SopA of the *E. coli* F plasmid, a 388-residue protein with a DNA-dependent ATPase activity, involved in the autoregulation of the *sopAB* operon (Mori et al., 1986). SpyB resembles SopB of the F plasmid, a DNA-binding protein that specifically binds to the F plasmid *sopC* locus (Mori et al.,

1986). Precisely 146 bp downstream from *spyB*, a sequence of 33 bp (ATTGGATATCCAGG TGACCGTGGTCCCAATTAC) is repeated twice, in the same order separated by 10 bp. Nucleotides 13 to 29 of these repeats can be aligned with the consensus sequence of the 12 directed repeats that form the partition site *sopC* of F (Mori et al., 1986; Herman and Schneider, 1992). From these similarities, it has been inferred that these repeats (called “*spyC*”) correspond to the partition site of the pYVe227 plasmid.

An Operon Encoding Arsenic Resistance: Conquest of a New Ecological Niche The pYVe227 plasmid of the low virulence strains of *Y. enterocolitica* (O:1,2,3, O:1,2, O:3, O:9 and O:5,27) contains a class-II transposon, Tn2502, which confers resistance to arsenite and arsenate (Neyt et al., 1997). This resistance involves four genes: three are the homologues to the *arsRBC* genes present on the *E. coli* chromosome but the fourth one, *arsH*, has no known homologue. ArsR is an arsenite-inducible transcriptional repressor, ArsB forms a transmembrane channel, and ArsC catalyzes the reduction of arsenate to arsenite, which is, in turn, expelled by the ArsB transport system. Protein ArsH could act as a regulator, even though this has never been shown. To our knowledge, this is the first example of a virulence plasmid carrying resistance genes (Neyt et al., 1997). The *ars* operon is not present on the pYVe227 plasmid of the more virulent “American” strains (serotypes O:4, O:8, O:13a, 13b, O:18, O:20 and O:21) of *Y. enterocolitica*. This suggests that the low virulence strains, which are distributed worldwide, constitute a single clone that probably emerged quite recently. At the present time, pigs represent the major reservoir of pathogenic strains of *Y. enterocolitica*, and pork meat is recognized as the major human contamination source (Tauxe et al., 1987; Lee et al., 1991; Epidemiology of *Y. enterocolitica*). Neyt et al. (1997) speculated that the *ars* transposon might have favored the establishment of a strain of *Yersinia* in pigs. Arsenic compounds were largely used before World War II as therapeutic agents to protect pigs from diarrhea caused by *Serpulina hyodysenteriae*.

Insertion-like Sequences The pYVe227 plasmid contains several ISs, some of which are vestigial (Iriarte and Cornelis, 1999a). Most of these belong to the IS3 family and they resemble IS222 of *Pseudomonas aeruginosa*.

THE 70-KB PLASMID OF *Y. PSEUDOTUBERCULOSIS* AND *Y. PESTIS* AND EVOLUTIONARY ASPECTS **An Overview** The virulence plasmid of *Y. pestis* has also been completely sequenced by two different

groups (Hu et al., 1998b; Perry et al., 1998). The sequence of the *Y. pseudotuberculosis* pIB1 has not been published yet but most of it is known (Persson et al., 1995). In general, the 70-kb plasmid is quite well conserved in the three species (Portnoy and Falkow, 1981a; Portnoy et al., 1981b; Biot and Cornelis, 1988; Hu et al., 1998b; Perry et al., 1998; Iriarte et al., 2002). All the 35 genes of the secretion-translocation apparatus are present in the very same order. The same effector genes are also present on the three plasmids, but they have been reshuffled. The ancillary functions of replication and partition of the three plasmids are also the same, indicating that they derive from a common ancestor.

Major Inversions The order of the genes is identical in pCD1 and pIB1, reinforcing the idea that *Y. pestis* and *Y. pseudotuberculosis* are extremely close. In contrast, half of the plasmid is inverted in pYVe227 (Biot and Cornelis, 1988). The inversion occurred between *yopH* and *sycH* on one side and between *ylpA* and *yopJ/yopK* on the other side. In addition, within the inverted half, the region containing the partition system, *yopE*, *sycE* and *sycH* also suffered an inversion, putting it back in the original orientation. Surprisingly, the two major inversions are not bordered by transposable elements.

Minor Inversions Minor rearrangements also occurred in other regions of the 70-kb plasmid. The gene encoding *YopM* represents a nice illustration of such rearrangements. Gene *yopM* itself shows some heterogeneity among different *Yersinia* isolates, probably because it encodes a protein with internal repetitions (Boland et al., 1998b). In addition, the orientation of *yopM* varies. The gene is oriented clockwise in *Y. enterocolitica* and anti-clockwise in *Y. pseudotuberculosis* and *Y. pestis*. The region upstream and downstream from *yopM* contains three long repeated sequences and putative open reading frames (ORFs; Reisner and Straley, 1992). Genetic recombinations between these repeats could explain the observed inversion of *yopM*.

Localized Mutations The *yadA* gene also underwent some modifications during evolution of the 70-kb plasmid. The *yadA* gene varies in the different serotypes of *Y. enterocolitica* resulting in proteins of different size. Most importantly, the *yadA* gene of *Y. pestis* has a single base pair deletion that results in a shift in the reading frame of the gene and a reduction of the half life of the mRNA resulting in the loss of the protein (Portnoy et al., 1984; Rosqvist et al., 1988; Skurnik and Wolf-Watz, 1989; Hu et al., 1998b).

The information available in databases also indicates that *ylpA* is a pseudogene in *Y. pestis* (Hu et al., 1998a; Perry et al., 1998).

YscM2, *YomA*, *PprA*, and *ORF80* are not encoded by pCD1 (Hu et al., 1998b; Iriarte and Cornelis, 1999a). According to the information available in the databases, the gene encoding *YomA* is also missing in pIB1 from *Y. pseudotuberculosis* and only a partial ORF encoding 166 amino acids with 100% identity to the N-terminus of *YomA* protein is found in the pYVe227 plasmid of *Y. enterocolitica* serotype O:3 and a short ORF encoding the first 53 amino acids of *YomA* is found in the pCD1 plasmid of *Y. pestis* (accession number X13882; Skurnik and Wolf-Watz, 1989; Hu et al., 1998b; Iriarte et al., 2002).

Duplication The pYVe227 plasmid from *Y. enterocolitica* contains two copies of *yscM* (Stainier et al., 1997), a hypothetical player of the negative regulatory loop (Rimpiläinen et al., 1992). In contrast, there is only one copy of the homologue *lcrQ* in *Y. pseudotuberculosis* and *Y. pestis*. Thus, *yscM* was presumably duplicated after the *Y. pestis* and *Y. pseudotuberculosis* diverged (see below).

Lack of the ARS Resistance Genes As we mentioned before, the pYV plasmid of low virulence pathogenic *Y. enterocolitica* strains harbor a transposon encoding arsenite resistance (Neyt et al., 1997). This transposon is absent from pIB1 and pCD1, which is in agreement with the hypothesis of its recent acquisition by a pYV plasmid from *Y. enterocolitica* (see above).

Conclusions The three plasmids clearly have a common ancestor of the RepFII A type. The pYVe227 plasmid is probably closer to this ancestor than pIB1 and pCD1 because *yopH* and *sycH* are still associated, and *yadA* and *ylpA* are intact (China et al., 1990; Stainier et al., 1997; Iriarte and Cornelis, 1999a).

The fact that the pYVe227 plasmid contains the remains of a transfer operon suggests that, in its origin, the plasmid was conjugative. The *tra* genes that are still conserved such as *ylpA* homologous to *traT* and *nuc* could have evolved to fulfill another, still unknown function.

As it is generally the case for the large plasmids, stability of the 70-kb plasmid is assured by a partition system. However, unlike large plasmids (such as F, R1 and R438), the 70-kb plasmid does not have a system like *hok/sok*, *isrB* or *pnd*, which kills plasmid-free segregants (Nielsen et al., 1991; Gerdes et al., 1992). This observation is in perfect agreement with the fact that *Yersinia* easily gives pYV⁻ segregants when plated at 37°C on a medium deprived of Ca²⁺ (Biot and Cornelis, 1988).

High-pathogenicity Island (Elisabeth Carniel)

GENERAL CHARACTERISTICS OF THE HPI One of the major differences between low-pathogenicity strains (which are not mouse-lethal and induce intestinal infections of moderate severity in humans), and high-pathogenicity strains (which are mouse-lethal and cause severe systemic infections in humans) of *Yersinia* is the presence of a “high-pathogenicity island” or “HPI” (Carniel et al., 1996), which can be considered as an iron-uptake island (Carniel, 2001). This designation comes from the original observation that the presence of this island is strictly correlated with the expression of a high-pathogenicity phenotype (De Almeida et al., 1993). The HPI is restricted to certain subgroups of the three pathogenic species of *Yersinia*: serotypes I and III (with a 9-kb truncation at the left-hand part) of *Y. pseudotuberculosis* (Rakin et al., 1995; Buchrieser et al., 1998a), biotype 1B of *Y. enterocolitica*, and all three biotypes of *Y. pestis* (De Almeida et al., 1993).

All criteria defining a pathogenicity island (Hacker et al., 1997) are fulfilled by the HPI: 1) it is a large chromosomal DNA fragment (36 kb in *Y. pseudotuberculosis* and *Y. pestis*, and 43 kb in *Y. enterocolitica*), 2) it carries genes essential for the expression of a high-pathogenicity phenotype, 3) it incorporates several repeated sequences (IS1328, IS1329, IS1222 and IS1400, or IS100) and a mobility gene (bacteriophage P4-like integrase gene), 4) it is bordered on one side by a *tRNA* locus (*asn tRNA*), 5) the G+C content

of the open reading frames composing the yersiniabactin locus (60%) is much higher than that of the core genome (46–50%), and 6) the island is mobile in some strains.

The HPI confers on the bacteria the ability to capture iron ions bound to eukaryotic molecules via a high-affinity, iron-chelating system (e.g., siderophore) called “yersiniabactin” (Heesemann, 1987), and subsequently to disseminate in mammalian hosts and to cause systemic infections. The siderophore yersiniabactin is a small molecule (482 Da), which belongs to a subgroup of phenolate siderophores and contains a phenolic group as well as one thiazolidine and two thiazoline rings (Haag et al., 1993; Drechsel et al., 1995; Chambers et al., 1996; Gehring et al., 1998a). Its structure is identical in *Y. enterocolitica* and *Y. pestis* (Perry et al., 1999), and closely resembles those of pyochelin and anguibactin produced by *Pseudomonas aeruginosa* and *Vibrio anguillarum*, respectively. The yersiniabactin molecule has an extremely high affinity for ferric iron ($K_D = 4 \times 10^{-36}$; Gehring et al., 1998a; Perry et al., 1999). The biochemical structures and functions of different components of the machinery involved in the nonribosomal biosynthesis of yersiniabactin are currently under investigation (Suo et al., 1999; Suo et al., 2000; Suo et al., 2001; Keating et al., 2000a; Keating et al., 2000b; Ino and Murabayashi, 2001).

GENETIC ORGANIZATION OF THE HPI The HPI is composed of two functionally distinct parts (Fig. 36): the 30-kb right-hand highly conserved

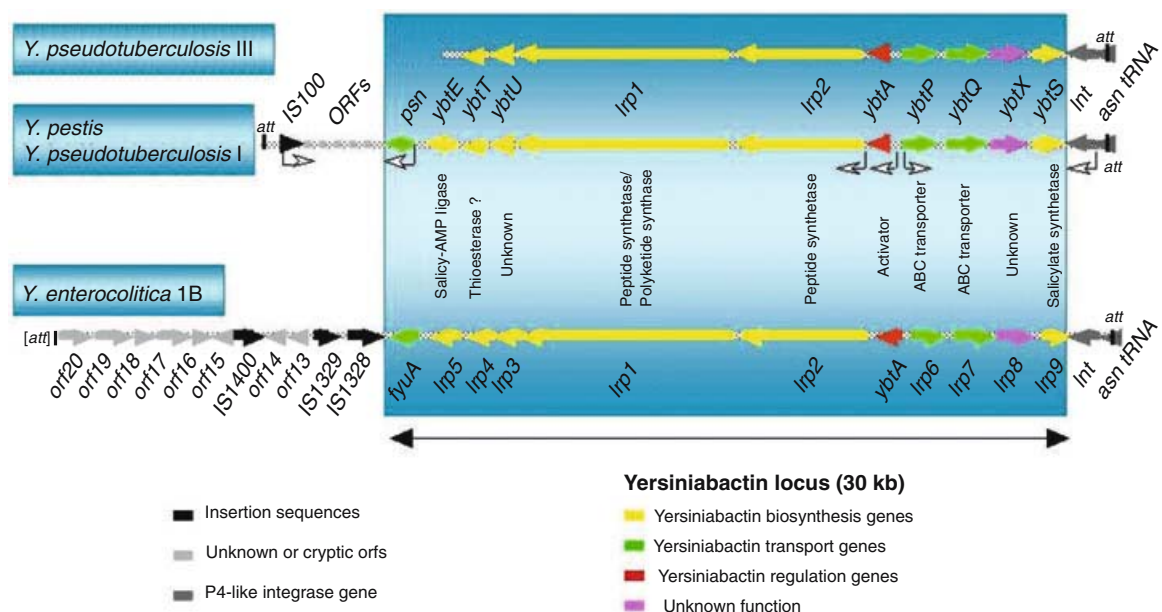

Fig. 36. Genetic organization of the HPIs of the three highly pathogenic species of *Yersinia*.

portion of the HPI, termed the “yersiniabactin locus,” and the left-hand part, which is variable in size and is much less conserved in the three highly pathogenic species.

The Yersiniabactin Locus This locus is composed of 11 genes, which can roughly be divided into three functional groups: yersiniabactin biosynthesis, transport into the bacterial cell, and regulation (Fig. 36).

The yersiniabactin biosynthesis genes are extremely conserved in highly pathogenic *Yersinia* species (> 98% nt identity; Buchrieser et al., 1998a; Gehring et al., 1998a; Rakin et al., 1999), and components of the yersiniabactin systems are interchangeable among the three species (Carniel et al., 1992; Perry et al., 1999). However, *Y. pseudotuberculosis* strains of serotype III lack the left-hand part of the yersiniabactin locus carrying the *ybtE* and *psn* genes. Formation of yersiniabactin occurs via a mixed polyketide synthase, nonribosomal peptide synthetase strategy that assembles the siderophore in modular fashion from salicylate (Guilvout et al., 1993; Gehring et al., 1998a; Gehring et al., 1998b; Suo et al., 1999; Keating et al., 2000a; Keating et al., 2000b). At least seven gene products are involved in yersiniabactin biosynthesis (Fig. 36): YbtU, YbtT, YbtE, YbtS, and the high-molecular weight proteins HMWP2 and HMWP1 (Geoffroy et al., 2000).

Three genes are involved in yersiniabactin-mediated internalization of iron: *psn*, *ybtP* and *ybtQ* (Fig. 36). Psn, a TonB-dependent outer-membrane protein, acts as a receptor for both yersiniabactin and the bacteriocin pesticin (Heesemann et al., 1993a; Fetherston and Perry, 1994; Rakin et al., 1994; Fetherston et al., 1995). YbtP and YbtQ are inner-membrane permeases required for translocation of iron into the bacterial cytosol (Gehring et al., 1998a; Fetherston et al., 1999). These two proteins are unique among the subfamily of ABC transporters of iron, since they both contain an amino-terminal membrane-spanning domain and a carboxy-terminal ATPase (Fetherston et al., 1999).

Several systems regulate expression of the yersiniabactin locus: 1) YbtA, a regulator of the AraC family of transcriptional regulators, activates expression from the *psn*, *irp2* and *ybtP* promoters, but represses expression of its own promoter (Fetherston et al., 1996); 2) the siderophore yersiniabactin may upregulate its own expression along with that of *psn* and *ybtPQXS* at the transcription level (Fetherston et al., 1996; Fetherston et al., 1999; Bearden et al., 1997; Peludat et al., 1998; Perry et al., 1999), probably by binding to the YbtA activator (Geoffroy et al., 2000); and 3) the Fur regulator represses transcription of the four promoter regions of the

yersiniabactin locus in the presence of iron (Guilvout et al., 1993; Rakin et al., 1994; Gehring et al., 1998a).

The Right Border of the HPI This region, well conserved among the three pathogenic *Yersinia* species, contains a gene homologous to that of the integrase of bacteriophage P4 and an asparagine tRNA (*asn tRNA*) locus (Carniel et al., 1996; Buchrieser et al., 1998a; Buchrieser et al., 1998b; Buchrieser et al., 1999; Bach et al., 1999; Hare et al., 1999; Rakin et al., 1999). The P4-like *int* gene may be potentially functional in *Y. pestis* and *Y. pseudotuberculosis*, but its homologue in *Y. enterocolitica* contains a premature stop codon that results in a truncated peptide (Bach et al., 1999; Rakin et al., 1999). The border of the HPI is formed by a 17-bp sequence homologous to the attachment site (*att*) of bacteriophage P4 and located at the 3' extremity of the *asn tRNA* locus.

The Left-hand Region of the HPI In contrast to the highly conserved 30-kb yersiniabactin locus, the left-hand portion of the island is polymorphic among various strains and species of *Yersinia* (Fig. 36) and can be subdivided into two main groups: *Y. enterocolitica* 1B on the one hand, and *Y. pestis* and *Y. pseudotuberculosis* I on the other hand (Rakin et al., 1995). This region is not yet defined in *Y. pseudotuberculosis* strains of serotype III.

In *Y. enterocolitica* 1B, the left-hand part, which extends 12.8 kb downstream of the *psn* gene, contains a cluster of four IS elements (IS1328, IS1329, a portion of IS1222 interrupted by IS1329, and IS1400), and seven other ORFs that have no significant homologies to any known gene (Rakin et al., 1995; Rakin et al., 1999; Rakin et al., 2000; Carniel et al., 1996). This region is not well conserved among various *Y. enterocolitica* 1B strains (Carniel et al., 1996). The left-hand extremity of the *Y. enterocolitica* HPI is delimited by a pseudo *att*-like site that represents a degenerate form of the 17 bp *att*-like site present at the other extremity of the island (Bach et al., 1999).

In *Y. pestis* and *Y. pseudotuberculosis* I, the left-hand portion of the HPI is approximately 5 kb long (Fig. 36). It carries one insertion sequence, designated “IS100” (Fetherston and Perry, 1994; Podladchikova et al., 1994; Prentice and Carniel, 1995) and several short ORFs homologous to phage genes (Buchrieser et al., 1999; Rakin et al., 1999). The left-hand part of the HPI terminates 248 and 516 bp downstream of the IS100 sequence in *Y. pseudotuberculosis* and *Y. pestis*, respectively (Buchrieser et al., 1998a; Buchrieser et al., 1999; Rakin et al., 1999). It has been suggested that the larger size of the region between the IS100 gene and the border of

Abbreviations: HPI, high pathogenicity island; IV, intravenously; SC, subcutaneously; and IG, intragastrically.

the HPI in *Y. pestis* is a scar of the ancient insertion and excision of an IS630-like element in this region (Hare et al., 1999). The left border of the island is determined by a perfectly conserved 17-bp sequence, repeated at the other extremity of the HPI (Buchrieser et al., 1998a; Buchrieser et al., 1999; Hare et al., 1999).

ROLE OF THE HPI IN *YERSINIA* PATHOGENESIS

Microbial pathogens must adapt to the iron-restricted milieu found in vivo. The successful establishment of disease depends on the ability of the invading organism to develop high-affinity iron transport systems. Numerous clinical reports have shown that *Y. enterocolitica* strains of biotypes 2 and 4, naturally deprived of the HPI-borne yersiniabactin system, are responsible for moderate intestinal symptoms, but can cause systemic infections if the patients are iron-overloaded (during thalassemia, hemochromatosis, etc.; Other putative or proven virulence factors, paragraph iron uptake systems). Similarly, in the mouse experimental model of infection, these strains do not kill mice at low doses unless iron or the siderophore Deferoxamine is provided exogenously (Robins-Browne and Prpic, 1985a). In contrast, *Y. enterocolitica* 1B strains, which carry the high-affinity iron-capture yersiniabactin system, are inherently lethal for laboratory animals at low doses. Therefore, although other as yet unidentified factors may participate in the high-pathogenicity phenotype, one of the major differences between low- and high-pathogenicity *Yersinia* lies in their ability to capture the iron molecules necessary for their systemic dissemination in the host via the yersiniabactin system.

Initially, indirect evidence for a role of the HPI in the expression of a high pathogenicity phenotype was obtained through the observation of a strict correlation between the presence of HPI-specific genes or products and the level of pathogenicity of a large number of natural *Yersinia* isolates (Harrison et al., 1980; Carniel et al.,

1987; Carniel et al., 1989; Heesemann, 1987; De Almeida et al., 1993; Heesemann et al., 1993a; Chambers and Sokol, 1994; Rakin et al., 1995). Definitive proofs for its role in *Yersinia* pathogenesis were acquired by mutagenizing various HPI-borne loci. Abolition of yersiniabactin production by uncharacterized Tn5 insertions in the chromosome of a *Y. enterocolitica* 1B resulted in an alteration of the pathogenicity of the mutants (Heesemann, 1987). Specific mutagenesis of various genes involved in yersiniabactin-mediated iron-uptake led to a reduction of virulence of the mutant for mice (Table 28). This decrease in virulence was much more important when the mutant was injected subcutaneously (SC) or intragastrically (IG) than when it was injected intravenously (IV). Similar results were recently obtained with a *Y. pseudotuberculosis* strain where the entire HPI was precisely excised from the chromosome (Lesic et al., 2002). The HPI thus seems to play a crucial role to allow the bacteria to disseminate from a peripheral portal of entry and to invade its host.

MOBILITY OF THE HPI The HPI inserts specifically into an *asn tRNA* locus present in three copies on the *Yersinia* chromosome (Buchrieser et al., 1998a). The *Y. pseudotuberculosis* HPI can insert into any of these three copies (Buchrieser et al., 1998a), while the HPI of *Y. enterocolitica* is inserted specifically into the *asnT* locus (Carniel et al., 1996; Rakin et al., 1999), and that of *Y. pestis* into another copy of this locus (Hare et al., 1999). The 3' end of each chromosomal *asn tRNA* locus contains a 17-bp sequence homologous to the *att* site of bacteriophage P4 (Buchrieser et al., 1998a; Rakin et al., 2001). It is likely that original integration of the HPI occurred by site-specific recombination between one of these *att*-like sites on the *Yersinia* chromosome and its homologue on an episome carrying the HPI. Integration of the HPI into the chromosome produces a duplication of the *att*-like site at each extremity of the island, while

excision of the HPI regenerates a unique *att*-like sequence at the junction site and restores an intact *asn tRNA* locus (Buchrieser et al., 1998a).

The *Yersinia* HPI also carries a gene homologous to the integrase gene (*int*) of phage P4. The presence of the *int* and *att* loci is necessary and sufficient for the integration of the HPI into the bacterial chromosome. Indeed, cloning of these two loci on a suicide plasmid engendered its integration into any of the chromosomal *att* sites (Rakin et al., 2001). These two loci are also involved in HPI excision from the chromosome.

In *Y. enterocolitica* 1B, where the *int* gene is naturally mutated and one of the two *att* sites is degenerate, no strain containing a precisely deleted island could ever be detected (De Almeida et al., 1993; Rakin et al., 1995; Bach et al., 1999), suggesting an essential role of these loci in HPI deletion.

This role was confirmed by demonstrating that mutagenesis of the integrase gene of *Y. pseudotuberculosis* abolishes HPI excision (Lesic et al., 2002). In this latter species, the frequency of spontaneous HPI excision from the chromosome is ca. 10^{-4} for strain IP32637 (Buchrieser et al., 1998a), but may vary greatly depending on the strain (Lesic et al., in preparation). The fact that in individual colonies of the same isolate, the HPI could be found inserted into one or another *asn tRNA* locus suggests that this element has retained the ability to excise from and reinsert into another location on the *Y. pseudotuberculosis* chromosome (Buchrieser et al., 1998a).

The excision of the *Y. pestis* HPI is not precise but occurs as part of a much larger chromosomal deletion of 102 kb designated “*pgm* locus” (Fetherston et al., 1992), which encompasses most of the HPI and extends further rightward over a 68-kb region. Spontaneous excision of the *pgm* locus occurs at very high (2×10^{-3}) frequencies (Hare and McDonough, 1999) by homologous recombination between the two *IS100* flanking copies (Fetherston et al., 1992; Fetherston and Perry, 1994). The HPI of *Y. pestis* has the potential to virtually excise precisely from the chromosome since it possesses a copy of the *att* locus at each extremity, and an intact P4-like integrase gene (Buchrieser et al., 1998a; Hare et al., 1999), but its deletion is possibly masked by the high deletion frequency of the 102-kb *pgm* locus.

PRESENCE OF THE HPI IN OTHER SPECIES OF ENTEROBACTERIA Although the HPI was initially found and described in the genus *Yersinia*, it was subsequently identified in other members of the Enterobacteriaceae family such as *E. coli*, *Enterobacter cloacae*, various species of *Klebsiella* (*K. pneumoniae*, *K. rhinoscleromatis*, *K. ozaenae*, *K. planticola* and *K. oxytoca*), and of

Citrobacter (*C. diversus* and *C. koseri*; Schubert et al., 1998; Schubert et al., 2000b; Karch et al., 1999; Bach et al., 2000; Johnson and Stell, 2000; Xu et al., 2000; Clermont et al., 2001; Gophna et al., 2001; Johnson et al., 2001), and in non-I serotypes of *Salmonella enterica* (Oeschläger et al., 2002). The HPI is the only pathogenicity island identified until now in different bacterial genera.

The HPI of *E. coli* and *Yersinia* are highly conserved, as demonstrated by the sequences of portions of *irp2* and *fyuA* that are more than 98% identical in the two genera (Rakin et al., 1995; Schubert et al., 1998; Schubert et al., 1999b). The *E. coli* HPI is more closely related to the island of *Y. pestis* and *Y. pseudotuberculosis* than to that of *Y. enterocolitica* (Rakin et al., 1995). The overall organization of the HPI is also well conserved among the different HPI-positive enterobacteria, although minor differences at the extremities of the island may be noted (Bach et al., 2000). An intact P4-like *int* gene is commonly present and shares 94% shiga toxin-producing *E. coli* (STEC) to 99% uropathogenic *E. coli* (UPEC) identity with the *Y. pestis* homologue (Karch et al., 1999; Schubert et al., 1999b). Partial or total deletion of *int* has been reported in a few enterobacteria isolates (Karch et al., 1999; Bach et al., 2000; Gophna et al., 2001), suggesting a process of stabilization of the island on the chromosome of these bacteria. The left-hand boundary of the HPI is more variable among enterobacteria. Some *E. coli* strains that contain an *irp2* locus lack the *fyuA* gene, while some STEC isolates that do harbor the *fyuA* locus still do not synthesize the protein (Karch et al., 1999), indicating that *FyuA* may be dispensable under certain circumstances. In addition to *fyuA*, the *IS100* element and the *att* boundary of the HPI may also be missing in some *E. coli* (Schubert et al., 1998; Schubert et al., 1999a; Karch et al., 1999; Bach et al., 2000), a situation reminiscent of the HPI of *Y. pseudotuberculosis* III. With very few exceptions (Bach et al., 2000; Clermont et al., 2001), the enterobacteria HPI is integrated into the *asnT* locus, which contains a perfectly conserved *att*-like site.

In *E. coli*, the HPI is found in a wide variety of pathotypes: enteroaggregative (EAEC), enteropathogenic (EPEC), enteroinvasive (EIEC), enterotoxigenic (ETEC), enterohemorrhagic (EHEC)/STEC (serotypes O:26:H11/H- and O:128:H2/H-), UPEC, and septicemic and meningitis *E. coli* (Schubert et al., 1998; Karch et al., 1999; Clermont et al., 2001; Gophna et al., 2001). There is a strong association between the presence of the HPI and the severity of the infection. The HPI is more frequently associated with pathogenic strains than with saprophytic clinical isolates (Schubert et al., 1998). In the *E. coli*

reference (ECOR) collection, 93% of the strains belonging to the pathogenic groups B2 and D, versus less than 30% of the strains belonging to nonpathogenic groups A and B1 harbor the HPI (Johnson and Stell, 2000; Clermont et al., 2001; Johnson et al., 2001). Furthermore, carriage of the HPI is extremely frequent in *E. coli* strains causing severe forms of infection: 89% of serotype 078, and 100% of serotype 02 *E. coli* strains isolated from poultry with acute septicemia (Gophna et al., 2001), 70–100% of clinical strains isolated from urine or blood (Schubert et al., 1998; Schubert et al., 2000b; Gophna et al., 2001), and 100% of *E. coli* strains that caused neonatal meningitis in humans (Clermont et al., 2001; Gophna et al., 2001) possessed the HPI.

However, some HPI-positive *E. coli* were isolated as commensal microorganisms from asymptomatic carriers. The same holds true for *Citrobacter*, *Enterobacter* and *Klebsiella*, which may persist as saprophytic bacteria in healthy humans. These observations thus suggest that the HPI per se is not sufficient to cause severe infections in humans, and that additional bacterial and/or host factors may be required. In *Yersinia*, for instance, in the absence of the pYV virulence plasmid, the organisms cannot establish an infection, even if they harbor the HPI. In the case of usually commensal enterobacteria, it may be hypothesized that immune suppression may be the host factor that enables HPI-bearing organisms to disseminate in vivo and cause nosocomial infections, while HPI-negative organisms would remain in their initial niche. Therefore, as recently suggested (Hacker and Carniel, 2001), the presence of the HPI is a key factor in determining whether the bacterium will remain localized at the site of infection or will invade its host, but this capability may also be dependent on the genetic background of the HPI-bearing bacterium and on the host status.

Invasin (Ralph Isberg)

INVASIN WITHIN THE INTESTINE Shortly after they are ingested, the enteropathogenic *Yersinia* establish a close relationship with host cells that is presumably maintained throughout the disease process. Within the intestine, the bacteria are internalized by M cells (Autenrieth and Firsching, 1996a; Marra and Isberg, 1997; Clark et al., 1998), which lay over the lymphoid follicle-associated epithelium (Neutra, 1999; Immunology and Physiopathology). After translocation across the M cell into these lymphoid follicles, there is no evidence for any further localization of the bacteria within host cells (Heesemann et al., 1993a).

At the very earliest stages of disease, the organism establishes contact with host cell β 1-

chain integrin receptors on the surface of M cells (Marra and Isberg, 1997; Clark et al., 1998). The primary protein responsible for this interaction is the bacterial invasin protein, which binds to at least five different integrin receptors (α 3 β 1, α 4 β 1, α 5 β 1, α 6 β 1 and α v β 1 (Isberg and Leong, 1990b) and is responsible for the ability of the organism to enter M cells in the intestine. Invasin mutants unable to bind to integrin receptors do not enter M cells and do not efficiently translocate into the lymphoid follicle (Pepe and Miller, 1993; Marra and Isberg, 1997).

STRUCTURE OF INVASIN Invasin is able to promote efficient uptake of bacteria into normally nonphagocytic cultured cell lines, reminiscent of what is observed with intestinal M cells. The *Y. pseudotuberculosis* invasin is a member of the bacterial intimin/invasin family, which consists of cell adhesion proteins found on the surface of a variety of enteropathogens (McGraw et al., 1999). The N-terminal 503-residues are highly conserved among family members and are important for surface localization of the protein (Leong et al., 1990). The divergent C-terminal region contains the determinants involved in receptor recognition and consists of a series of structural repeats that show little sequence homology to each other. At the C-terminus of the *Y. pseudotuberculosis* protein, four immunoglobulin-like (Ig-like) repeats are arrayed in tandem on the bacterial cell surface, followed by a C-type lectin-like domain (D5; CTLD) at the extreme C-terminus (Hamburger et al., 1999). The CTLD (D5) and the most upstream Ig domain (D4) form a large interface with each other, producing a superdomain that acts as a mammalian cell adhesion module.

The analysis of point mutations in cell adhesion superdomain reveals that two noncontiguous sites are involved in binding integrin receptors. The first region is localized in a disulfide loop and centered around the residue Asp911 (Leong et al., 1995). It has been proposed that this residue performs a similar role to the Asp1495 located in the arg-gly-asp sequence of fibronectin (Fn), which is critical for the binding of this protein to the integrin receptor α 5 β 1 (Leahy et al., 1996). The second region is centered around residue Asp811, although residue changes in this region have much weaker effects than seen with Asp911 (Saltman et al., 1996). Fibronectin also has a binding determinant not contiguous to arg-gly-asp, called the “synergy region,” which appears to play a role in supporting integrin binding (Aota et al., 1994). Thus, although there is no detectable sequence similarity between invasin and fibronectin, sequence determinants involved in receptor recognition appear to be similar.

INVASIN-PROMOTED UPTAKE INTO CULTURED CELLS Three important factors enhance invasin-mediated uptake: 1) high-affinity binding of integrin receptors by the D4-D5 superdomain (Tran Van Nhieu and Isberg, 1993); 2) the ability of invasin monomers to undergo homotypic interactions (Dersch and Isberg, 1999); and 3) an increase in the concentration of integrin receptors available to bind invasin (Tran Van Nhieu and Isberg, 1993; Dersch and Isberg, 1999). Mutations that lower the affinity of the protein for receptors, deletion of a region of invasin necessary for homotypic interaction, and depletion of integrin receptors from the host cell all severely depress bacterial uptake, causing extra-cellular adhesion of the bacteria.

HIGH-AFFINITY BINDING OF INTEGRIN RECEPTORS

The most striking difference between invasin and fibronectin binding is the significantly higher affinity of invasin-receptor binding. This property is both critical for the protein to promote uptake, as well as a central virulence determinant for the microorganism. Mutation of Asp911 to glutamate in invasin allows *Y. pseudotuberculosis* to adhere to cells, but the lowered affinity caused by the lesion prevents bacteria from entering M cells and colonizing Peyer's patches in the mouse intestine (Marra and Isberg, 1997).

THE ROLE OF INVASIN HOMOTYPIC INTERACTIONS

The monomeric cell adhesion domain of invasin is inefficient at promoting uptake, whereas dimerization of this superdomain is able to promote uptake. Deletion analysis of the *Y. pseudotuberculosis* invasin indicates that one of the immunoglobulin (Ig) domains (called "D2") promotes the homotypic interaction necessary for efficient uptake. The *Y. enterocolitica* invasin protein, which lacks D2, is much less efficient at promoting uptake than the *Y. pseudotuberculosis* protein (Dersch and Isberg, 2000). The rate of recruitment of tyrosine-phosphorylated proteins to the phagocytic cup is considerably enhanced by dimerization of invasin, which may be a reason for the importance of multimerization (P. Dersch, personal communication).

THE IMPORTANCE OF SUBSTRATE AND RECEPTOR DENSITY

By increasing the concentration of both invasin and integrin receptors, one can partially bypass the requirements for high receptor-substrate affinity and multimerization. Bacteria expressing high levels of invasin derivatives lacking D2 can be internalized at efficiencies approaching that of bacteria expressing similar levels of wildtype protein (Dersch and Isberg, 2000). Presumably, placing receptor-substrate contacts in sufficiently close proximity allows intracellular signals necessary for uptake to be

sent from the phagocytic cup. At lower invasin concentrations, such signals would require dimerization of the protein.

SUMMARY The physical properties of the invasin protein make it uniquely efficient at promoting uptake by engaging integrin receptors. Signaling events that lead to uptake of the bacteria as a consequence of integrin engagement are less well defined than the determinants of adhesivity. Presumably, integrin engagement leads to actin rearrangements that result in engulfment of the bacterium. Recent work indicates that signaling from the integrin via the small GTPase Rac1 is critical for sending information necessary for uptake. Future work will certainly involve determining the nature of the signals within the mammalian cell that leads to internalization.

Urease (Michel Simonet)

All *Yersinia* species, except *Y. pestis*, are able to use urease to hydrolyze urea to ammonia and carbon dioxide. Urease, a trimeric protein complex requiring nickel ions to be active (metalloenzyme), is exclusively located in the bacterial cytosol. De Koning-Ward and Robins-Browne (1997) showed that *Yersinia* urease is a novel type of bacterial urease because 1) it is maximally active at acidic pH and 2) it has a high affinity for urea, with an extremely low K_m value.

The genes required for urease biosynthesis have been characterized in the three pathogenic species (GenBank accession numbers {L24101} for *Y. enterocolitica*, {U40842} for *Y. pseudotuberculosis* and {AF095636} for *Y. pestis*). Three adjacent genes, *ureA*, *ureB* and *ureC*, encode the structural subunits, UreA (11 kDa), UreB (16–18 kDa) and UreC (61 kDa), which together form an inactive form of the enzyme (urease apoenzyme). The incorporation of nickel ions into the enzymatic catalytic site, which is located in UreC, requires at least four additional genes (*ureE*, *ureF*, *ureG* and *ureD*) that are contiguous to the chromosomal structural genes. As expected, the gene cluster is highly homologous between pathogenic *Yersinia* species (especially for *Y. pseudotuberculosis* and *Y. pestis*), and the structural genes are more highly conserved than the accessory genes (De Koning-Ward et al., 1994; Sebbane et al., 2001). Several genetic features suggest that *ure* genes are arranged in an operon-like manner, but it is not known whether they form a single (*ureABCEFGD*) or two polycistronic units (*ureABC* and *ureEFGD*). *Yersinia pestis* produces an inactive form of urease; this is due to the presence of one additional G residue in a poly G stretch which introduces a premature stop codon in *ureD* and leads to the truncation

of the accessory protein, UreD (Sebbane et al., 2001).

Unlike in most bacterial species, the expression of the *Yersinia* urease gene cluster is not induced by nitrogen limitation or by urea (De Koning-Ward and Robins-Browne, 1997). This is consistent with the absence of a binding site for the alternative sigma factor, σ^{54} , which governs transcription of nitrogen-regulated genes, within the *ureA* promoter region. Additionally, unlike some bacterial urease gene clusters, no urea-inducible activator gene (*ureR*) has been identified upstream of *ureA* in *Yersinia* species (Mobley et al., 1995). *Yersinia*'s ureolytic activity is growth phase-dependent and is optimal during the stationary phase, at both 28 and 37°C; the regulatory gene involved has not been identified yet, but it is not the gene encoding the RpoS σ factor.

Nonpathogenic and pathogenic (except *Y. pestis*) yersiniae are soil- and water-dwelling microorganisms. Urea is present in these environments and represents the main nitrogenous waste product of mammals; its degradation by urease provides bacteria with ammonium ions, an easily assimilable nitrogen source (Mobley and Hausinger, 1989). Therefore, the primary use of urease probably is to allow *Yersinia* spp. to live as saprophytes. However, it has been suggested that urease may also contribute to the pathogenesis of enteropathogenic species *Y. enterocolitica* and *Y. pseudotuberculosis* by protecting the microorganisms during their passage through the stomach. This is supported by the fact that in vitro, the enzyme is active at acidic pH and in the presence of low concentrations of urea, such as those found in the gastric juice. Isogenic urease-deficient mutants from both species were significantly disabled in acid stress conditions in vitro when compared to the wildtype strains, thus confirming this hypothesis (De Koning-Ward and Robins-Browne, 1995; Young et al., 1996; Riot et al., 1997). Furthermore, in an experimental model of murine oral infection, it was found that less urease-negative *Y. enterocolitica* mutants were recovered from the ileum of mice 90 min after the ingestion of contaminated drinking water or by gavage than wildtype *Y. enterocolitica* (De Koning-Ward and Robins-Browne, 1995); however, this difference was not observed with the corresponding *Y. pseudotuberculosis* mutant (Riot et al., 1997).

Enteric infection by *Y. pseudotuberculosis* and particularly *Y. enterocolitica* is sometimes complicated by reactive arthritis, especially when it occurs in patients positive for HLA-B27 (Clinical manifestations of *Y. enterocolitica* and Immunology). During a systematic search for bacterial arthritogenic factors, Mertz et al.

(1991) isolated a 19-kDa cationic protein from a *Y. enterocolitica* extract, which triggered joint inflammation when injected intra-articularly into presensitized rats. Probst et al. (1993) and Skurnik et al. (1993) concomitantly identified the 19-kDa protein as the UreB structural subunit of urease. Interestingly, this molecule was recognized as an immunodominant antigen by T lymphocytes from synovial fluids from humans with *Yersinia*-triggered reactive arthritis (Probst et al., 1993; Mertz et al., 1998; Appel et al., 1999); the 19-kDa protein also induced a significant humoral immune response in these patients, and the detection of serum antibodies has been shown to be useful for the diagnosis of reactive arthritis. These results suggest that UreB plays a role in the induction of arthritis. However, by using the experimental model of arthritis in the rat, Gripenberg-Lerche et al. (2000) found that the incidence of arthritis was almost the same when animals were inoculated intravenously with a wildtype *Y. enterocolitica* strain or with an isogenic *ureB*-deficient mutant; nevertheless, the authors noted that the onset of the illness was slightly delayed (but not significantly) and that the severity of joint inflammation was somewhat milder in rats infected with the mutant.

Lipopolysaccharide (Mikael Skurnik)

O-SEROTYPES OF YERSINIA Serotyping as a means of classifying *Salmonella* isolates was started as early as 1926 (White, 1926; Kauffmann, 1966) and is known as the Kauffmann-White scheme. The primary antigens in the scheme are the cell surface lipopolysaccharides (O-antigens) and the flagellin proteins (H-antigens). The O-antigen epitopes are determined by the type, arrangement, and condition of sugar residues in the repeated O-units. O-serotyping was applied to *Y. pseudotuberculosis* (5 serotypes) by Thal in 1954 (Thal, 1954) and to *Y. enterocolitica* (8 serotypes) by Winblad in 1967 (Winblad, 1973).

Since then, a substantial number of new serotypes have been added to both serotyping schemes: *Y. pseudotuberculosis* is now subdivided into 21 serotypes (Link 1: *Y. pseudotuberculosis* serotypes).

Serologically, *Y. pestis* strains are very homogeneous because their lipopolysaccharide (LPS) is rough, i.e., is lacking O-antigen (Brubaker, 1991). *Yersinia pestis* is apparently a very recently evolved clone of *Y. pseudotuberculosis* O:1b (Achtman et al., 1999; Skurnik et al., 2000) carrying a cryptic O-antigen gene cluster that is almost identical to that of *Y. pseudotuberculosis* O:1b (Skurnik et al., 2000).

Yersinia enterocolitica strains (including *Y. enterocolitica*-like species) are subdivided into

Table 29. Characteristics of *Y. pseudotuberculosis* serotypes.

^aSerotype-specific factor.

From Tsubokura and Aleksic (1995).

more than 70 serotypes (Link 2: Serotypes of *Y. enterocolitica* and related species).

While most *Y. pseudotuberculosis* serotypes appear to be associated with pathogenicity (Nagano et al., 1997b), this is true only for a few of *Y. enterocolitica* serotypes and biotypes.

CHEMICAL STRUCTURES The chemical structures of a number of *Yersinia* LPS molecules or different parts of the molecules have been determined. In most cases, the structure of the repeating O-unit has been resolved and only in a few cases the lipid A and core structures are known (Table 31). A peculiarity of *Y. enterocolitica* is the presence of a branching outer-core oligosaccharide in some *Y. enterocolitica* serotypes (e.g., O:3) expressing homopolymeric O-antigen (Skurnik et al., 1995). Only limited attention has been paid to the variability of the chemical structure of the LPS molecule with regard to different growth conditions, e.g., growth temperature, pH, ionic strength, etc. (Link 6. Regulation of LPS biosynthesis).

LPS BIOSYNTHESIS Gram-negative bacteria, like the members of the genus *Yersinia*, possess an outer membrane (OM). Most of the outer leaflet of the OM is occupied by LPS, which is com-

posed of two biosynthetic entities: 1) lipid A-core oligosaccharide, and attached to it, 2) O-specific polysaccharide also known as O-antigen. This division has relevance for the understanding of the biology and genetics of LPS; therefore, biosynthesis of these two LPS entities will be briefly discussed below (Link 3: LPS biosynthesis). Purified LPS is traditionally visualized by silver staining after SDS-PAGE (sodium dodecyl sulfate-polyacrylamide gel electrophoresis; Fig. 39), which reveals that bacteria express a heterogeneous population of LPS molecules with an Mr range of ~2000 to 50,000. This is because some LPS molecules do not carry any O-specific polysaccharide chains at all (Mr ~2000), while others do have a large variation in the lengths of the individual polysaccharide chains (Mr > 2000–50,000).

ENTEROBACTERIAL COMMON ANTIGEN AND LPS Enterobacterial common antigen (ECA) is a polysaccharide with a trisaccharide repeat unit expressed by all Enterobacteriaceae including *Yersinia* (Kuhn et al., 1988; Rick and Silver, 1996; Radziejewska-Lebrecht et al., 1998). ECA can be in three different structural forms: 1) linked to L-glycerophosphatide, 2) linked to LPS, or 3) as a cyclic structure (Rick and Silver, 1996). When linked to LPS, ECA is ligated specifically

Table 30. Some characteristics of the serotypes of *Y. enterocolitica* and related species.

Serotype	Species	Presence of the virulence plasmid	Presence of IVS in 23S rDNA	Presence of O:3 type LPS outer core
O:1	<i>Y. enterocolitica</i>	pYV	IVS	OC

Symbols and abbreviations: —, absent; pYV, ~70kb virulence plasmid of *Yersinia*;

IVS, a ~100-bp intervening sequence in the 23S rRNA gene; IVS/—, IVS is not present in all rRNA operons; OC, outer core oligosaccharide; and n.t., not tested.

From Skurnik (1985), Skurnik and Toivanen (1991), and Skurnik et al. (1995).

to those lipid A-core molecules that do not carry O-antigen. ECA biosynthesis on undecaprenyl phosphate (Und-P) takes place using similar reactions as described above for heteropolymeric O-antigen, and ligation to LPS is WaaL (O-polysaccharide ligase)-dependent (Rick and Silver, 1996). LPS-linked ECA is immunogenic

and antibodies against ECA are formed during infection.

GENETICS OF YERSINIA LPS BIOSYNTHESIS The genetic work with *Yersinia* has been performed mainly on the O-antigen gene clusters and the outer-core gene cluster of *Y. enterocolitica* O:3.

Genetics of the Lipid A and Core Biosynthesis

No genetic experiments have been reported on the lipid A and (inner) core biosynthesis genes of *Yersinia*. The basic genetic setup most likely resembles that of *E. coli* and *Salmonella*, however, very likely there will be differences in the regulation of the biosynthetic activities under different environmental conditions. The ongoing genomic sequencing work (*Y. pseudotuberculosis* O:1b and *Y. enterocolitica* O:8) will help to elucidate these issues.

Fig. 37. O-antigen. Chemical structure of *Y. enterocolitica* O:3 homopolymeric O-antigen (6d-altrose) and its linkage via the *N*-acetylglucosamine residue to inner core.

Fig. 38. Lipopolysaccharides (LPSs). Examples of LPS with homopolymeric (left) and heteropolymeric (right) O-antigens.

The Yersinia Heteropolymeric O-antigen Gene Clusters are Between hemH and gsk In *Yersinia*, all the studied heteropolymeric type O-antigen gene clusters are located between the *hemH* (ferrochelataase) and *gsk* (inosine-guanosine kinase) genes in the chromosome (Fig. 40 and Table 32). This location is different from that in *E. coli* and *S. enterica* where the O-antigen region is closely linked to the *gnd* (6-phosphogluconate dehydrogenase) locus, which is upstream of the *his* (histidine biosynthesis) operon at 45 min on the chromosomal map of *E. coli* K-12 and at centisome 45 on the *S. enterica* LT2 map (Berlyn et al., 1996; Sanderson et al., 1996).

Upstream of the *hemH* gene and the *Yersinia* O-antigen gene clusters is located the *adk* (adenylate kinase) gene, and downstream of the *gsk* gene, the *rosAB* and *ushA* (UDP-sugar hydrolase) genes, which are not directly involved in O-antigen biosynthesis. However, *rosAB* genes seem to be involved in regulation of O-antigen expression. For comparison and evolutionary considerations, in *E. coli* and *Salmonella*, the *adk*, *hemH*, *gsk* and *ushA* genes are located at 11

Fig. 39. Deoxycholate polyacrylamide gel electrophoretic (DOC-PAGE) analysis of lipopolysaccharide (LPS). Example of silver-stained LPS showing the heterogeneity of the LPS molecule population.

Fig. 40. The O-antigen gene cluster of *Y. pseudotuberculosis* O:1b. The gene cluster is located between the *hemH* and *gsk* genes and contains the genes for the biosynthesis of CDP-Par (*ddhDABC* and *pri*), GDP-Man (*manBC*) and GDP-L-Fuc (*gmd* and *fcl*). The *wbyIJKL* genes code for glycosyltransferases, *wzx*, *wzy* and *wzz*, for flippase, O-antigen polymerase, and O-antigen chain length determinant, respectively. Note that the cryptic O-antigen gene cluster of *Y. pestis* is almost identical to that of O:1b. From Skurnik et al. (2000).

min on the chromosome (Berlyn et al., 1996; Sanderson et al., 1996), and between *hemH* and *gsk*, these species carry only a single gene; in *E. coli*, the gene is *aes* coding for acetyl esterase (Peist et al., 1997).

The Yersinia Outer-core Gene Clusters are also Between hemH and gsk *Yersinia enterocolitica* serotype O:3 expresses a homopolymeric O-antigen; however, the O-antigen gene cluster is not located between the *hemH* and *gsk* genes (Zhang et al., 1993). Instead, this locus is occupied by the outer-core gene cluster (Skurnik et al., 1995). In *Y. enterocolitica* O:9 (a homopolymeric O-antigen), the outer core gene cluster is also present between the *hemH* and *gsk* genes (M. Skurnik, unpublished observation).

The Genomic Locations of the Homopolymeric O-antigen Gene Clusters are Unknown Thus far the only sequenced homopolymeric cluster is that of O:3 (Zhang et al., 1993) (Table 32).

REGULATION OF LPS BIOSYNTHESIS *JUMPstart and ops Sequences* The gene clusters for *Y. enterocolitica* O:3 outer core and O-antigen, *Y. enterocolitica* O:8 O-antigen, and *Y. pseudotuberculosis* O-antigen, carry a characteristic sequence called “JUMPstart sequence.” The JUMPstart sequence has been identified in all surface-polysaccharide biosynthesis gene clus-

ters and also for sex-pilus assembly and hemolysin production (Hobbs and Reeves, 1994; Nieto et al., 1996). The sequence is generally located downstream of functional promoters of the gene cluster. Nieto et al. reported that a short 8-bp sequence within the JUMPstart sequence plays a role in gene regulation, and this element was named “ops” (operon polarity suppressor). The ops element was shown to function as a cis-acting element that together with RfaH (a transcription antitermination factor that stimulates expression of LPS biosynthesis genes), F-factor sex pilus genes, and hemolysin genes, allows efficient transcription of long operons, especially of the distal genes (Bailey et al., 1996). It is postulated that ops endows RfaH with specificity for the subset of operons it is regulating. The role of ops and RfaH in regulation of *Yersinia* LPS operons has not yet been studied but they are very likely to be involved.

Temperature and Other Environmental Stimuli

A general feature of *Yersinia* is temperature-dependency of the LPS biosynthesis. Most striking is the almost complete downregulation of O-antigen expression in bacteria grown at 37°C; another is the modification of the lipid A structure with respect to its substitutions such as phosphate, aminoarabinose and acyl chains (Lakshmi et al., 1989; Aussel et al., 2000). Details of the regulatory mechanisms are not known.

Regulation of O:8 O-antigen Biosynthesis The expression of *Y. enterocolitica* O:8 O-antigen is similarly regulated by temperature such that more O-antigen is expressed on the cell surface at 25 than at 37°C. The regulation mechanism involves repression of the O-antigen cluster transcription at 37°C (Zhang et al., 1995). The *rosAB*

locus downstream of the O-antigen cluster, between the *gsk* and *ushA* genes is involved in the temperature regulated expression of O:8 O-antigen by an unknown mechanism (Zhang et al., 1995; Bengoechea and Skurnik, 2000). RosA is an efflux pump and RosB a K⁺/H⁺ antiporter (Bengoechea and Skurnik, 2000).

YERSINIA LPS AND VIRULENCE

LPS mutants No experiments on the role of LPS in the virulence of *Y. pseudotuberculosis* have been reported. On the contrary, a number of LPS mutants have been constructed in *Y. enterocolitica* strains and tested for virulence in animal experiments (Table 33). These include both O-antigen negative (rough) and outer core negative mutants. The results indicate that LPS mutant strains, either missing O-antigen or outer core, are attenuated. In signature-tagged-mutagenesis screens, mutations in the O-antigen gene cluster of *Y. enterocolitica* serotype O:8 were frequent, indicating also the critical role O-antigen plays during infection (Young and Miller, 1997; Darwin and Miller, 1999; Gort and Miller, 2000).

The LD₅₀ values for the rough *Y. enterocolitica* mutants were determined using intragastrically infected DBA/2 mice. All the mutants were less virulent than the wildtype strain; the LD₅₀ values for the rough mutants are about 50–100 times higher (Al-Hendy et al., 1992; Zhang et al., 1997); the outer core mutants are almost avirulent (Skurnik et al., 1999b). The outer core endowed the bacteria with resistance to cationic bactericidal peptides, and in coinfection experiments with the wildtype bacteria, the outer core mutant bacteria did not survive in deeper tissues as well as the wildtype bacteria, but they could colonize the Peyer's patches for 2–5 days. Similar coinfection experiments with rough mutants indicated that O-antigen is required for the initial colonization of the Peyer's patches (Skurnik, 1999a).

Biological Activities The endotoxic activity of *Yersinia* LPS has been addressed in some reports (Brubaker, 1972; Hartiala et al., 1989), but the role of *Yersinia* LPS in bacterial pathogenesis has received very little attention, and thus details of its biological role are far from being known. LPS isolated from different *Yersinia* species show differences in acyl-chain fluidity that correlate with OM permeability to hydrophobic agents (Bengoechea et al., 1998). Complete LPS also plays an important role in resistance against cationic antimicrobial peptides (Skurnik et al., 1999b). There are indications that O-antigen may play a role in resistance to complement-mediated killing (Wachter and Brade, 1989); however, LPS may also play some roles in adhesion to and invasion

of the host tissues and in the pathogenesis of reactive arthritis (Granfors et al., 1989; Granfors et al., 1998). LPS isolated from *Y. pseudotuberculosis* grown at 37°C, when integrated into artificial membranes, protects membrane vesicles from the complement activity (Porat et al., 1995). Passive immunization has been used to show that antibodies against the O-antigen, but not those against the core, protect mice against intravenous challenge of virulent bacteria (Skurnik et al., 1996).

Superantigens of *Y. pseudotuberculosis*

Superantigens are proteins that exhibit a highly potent polyclonal lymphocyte-proliferating activity for CD₄⁺, CD₈⁺ and sometimes $\gamma\delta$ ⁺ T lymphocytes. Unlike conventional antigens, superantigens bind as unprocessed proteins to the major histocompatibility complex (MHC) class II molecules present on the surface of antigen-presenting cells and to the variable region of the β chain (V β) of T-cell receptor (TcR; Marrack and Kappler, 1990). As a consequence, superantigens stimulate up to 30% of T cells and trigger the release of large amounts of pro-inflammatory and other cytokines, which cause deleterious effects in the host (Immunology). As they stimulate increased numbers of lymphocytes, superantigens may stimulate autoreactive T and B cells and thus initiate or worsen autoimmune diseases (Ulrich et al., 1995; Michie and Cohen, 1998).

Until the beginning of the 1990s, bacterial superantigens had only been identified in *Mycoplasma arthritidis* and the Gram-positive species *Staphylococcus aureus* and *Streptococcus pyogenes*. In 1993, it was discovered that a superantigen was released into the culture supernatant of *Y. pseudotuberculosis* strains (Abe et al., 1993; Miyoshi-Akiyama et al., 1993; Uchiyama et al., 1993). Interestingly, one of the producers was isolated from a patient with the clinical manifestations of Kawasaki syndrome, a systemic vasculitis of unknown cause and a pathophysiology that might involve a superantigen (Leung et al., 1995; Clinical manifestations of *Y. pseudotuberculosis* infections). The substance, purified from *Y. pseudotuberculosis* culture supernatants and inducing proliferation of human peripheral blood mononuclear cells at a concentration as low as 1 pg ml⁻¹, was designated "YPM" (for *Y. pseudotuberculosis*-derived mitogen). Cloning and sequencing of the YPM gene revealed a 456-base pair ORF that encodes a 151 amino acid precursor protein. After proteolytic cleavage of the 20 amino acid hydrophobic signal sequence, this precursor is processed into a mature form containing 131 residues (Yoshino et al., 1994a; Ito et al., 1995; Miyoshi-Akiyama et al., 1995; Abe and Takeda,

1997a). YPM does not share any homology with staphylococcal, streptococcal or mycoplasmal superantigens, and phylogenetic analysis clearly demonstrated that the *Y. pseudotuberculosis* superantigen is novel (Müller-Alouf et al., 2001). After the initial discovery of YPM, two variants were described: one (one amino acid shorter) is 83% identical to the original molecule, the most heterogeneous region lying between amino acid residues 65 and 86 (Ramamurthy et al., 1997a), whereas the other one differs only by a single amino acid substitution (His51 → Tyr; Carnoy and Simonet, 1999). These variants are now known as “YPMb” and “YPMc,” respectively, and the original superantigen is called “YPMa” (GenBank accession numbers: {D38523} and {D38638} for *ypmA*; {D88144} for *ypmB*). In 1992, the other enteropathogenic *Yersinia* species, *Y. enterocolitica*, was shown to produce superantigen (Stuart and Woodward, 1992). However, the T-cell specificity of the mitogen differs from that of YPM (Stuart et al., 1995) and genomic bacterial DNA could not hybridize to a *ypm* probe (Yoshino et al., 1995a; Carnoy and Simonet, 1999) indicating that the mitogen activity of *Y. enterocolitica* could not be attributed to *ypm*. The mitogenic substance of *Y. enterocolitica* has not yet been characterized. Surprisingly, *ypm* was not detected in *Y. pestis* (Miyoshi-Akiyama et al., 1995), although this species is genetically closely related to *Y. pseudotuberculosis*.

In vitro, the three YPM variants all selectively stimulate human T lymphocytes bearing $V_{\beta 3}$, $V_{\beta 9}$, $V_{\beta 13.1}$ and $V_{\beta 13.2}$ TcR variable regions, in an MHC class II-dependent manner (Abe et al., 1993; Uchiyama et al., 1993; Ramamurthy et al., 1997a). YPM also stimulates murine T-cells bearing $V_{\beta 7}$ and $V_{\beta 8}$ (Miyoshi-Akiyama et al., 1997). Both CD_4^+ and CD_8^+ cells are expanded, but CD_8^+ cells proliferate predominantly (Ito et al., 1995). YPM is a small superantigen (14.5 kDa) compared to the known bacterial superantigens, the size of which ranges from 20–30 kDa. The molecular mechanism by which YPM interacts with its two ligands, TcR and MHC class II molecules, is poorly known. By testing the blocking effect of synthetic peptides on YPM-triggered lymphocyte proliferation, it was found that a peptide corresponding to the first 23 amino acids of the *Y. pseudotuberculosis* superantigen was the best inhibitor; however, this peptide corresponding to the N-terminus region of the molecule only inhibited cell proliferation by 50% (Yoshino et al., 1996). Subsequently, mutational analysis of YPM revealed that the amino acids involved in ligand interactions are in fact scattered along the polypeptide chain rather than clustered into domains, and that two cysteine residues, located at positions 32 and 129, form a

disulfide bridge that is critical for the biological activity of YPM (Ito et al., 1999).

The superantigen-encoding gene is not present in all *Y. pseudotuberculosis* strains, and its distribution is independent of the O-serotype (Carnoy and Simonet, 1999). Interestingly, almost all isolates from the Far East and only one-fifth of European isolates were positive for *ypm* (Yoshino et al., 1995a; Carnoy and Simonet, 1999). In the Far East, human *Y. pseudotuberculosis* infection is frequently associated with a scarlet fever-like disease, Izumi fever, or Kawasaki-like syndrome (Somov and Martinevsky, 1973; Sato et al., 1983; Baba et al., 1991), which are seldom described in Europe and North America (Epidemiology of *Y. pseudotuberculosis*). However, there is currently no evidence of a correlation between these particular clinical manifestations and the presence of *ypm* in infecting strains.

YPM is produced by bacteria during the infectious process in the host: indeed, 1) anti-YPM antibodies are present in the blood of most humans infected with *Y. pseudotuberculosis*, with a higher titer in patients with systemic complications, and 2) the number of T cells bearing $V_{\beta 3}$ (but not $V_{\beta 9}$, $V_{\beta 13.1}$ and $V_{\beta 13.2}$) increases during the acute phase of the yersiniosis (Abe et al., 1997b). Furthermore, it was found that purified YPM (50 µg) can induce lethal shock in a mouse experimental model by producing tumor necrosis factor (TNF- α) and interferon γ (Miyoshi-Akiyama et al., 1997). The toxin also alters epithelial function in vitro by reducing active ion transport and increasing cellular permeability (Donnelly et al., 1999). Taken together, these results suggested a role for YPM in *Y. pseudotuberculosis* pathogenesis. In vivo comparison of the virulence of a wildtype strain and an isogenic mutant provided more relevant information in this field because this experimental approach evaluated the effect of the superantigen in the host in the context of the whole microorganism. Furthermore, the use of living *Yersinia* ensured the release of a physiological quantity of superantigenic toxin over a long period. In the murine model of systemic yersiniosis, the survival rate was higher for the animals infected with the superantigen-deficient strain than in animals infected with wild-type strain and lower virulence of the mutant could not be accounted for by a reduced bacterial growth in mouse tissues (Carnoy et al., 2000). The mechanisms by which YPM increases *Yersinia* virulence are not understood yet. A synergistic action of endotoxin with staphylococcal superantigen has been reported (Blank et al., 1997); therefore, one plausible explanation is that LPS effects are exacerbated by YPM.

Nucleotide sequence analysis revealed that the guanine and cytosine (G+C) content of *ypm*

was 35 mol%, whereas the G+C content of the *Y. pseudotuberculosis* genome is higher (47 mol%). This suggests that during evolution, *Y. pseudotuberculosis* obtained *ypm* from microorganisms with low G+C contents. The superantigen-producing species, *S. aureus*, *S. pyogenes* and *M. arthritidis*, are good candidates. However, the codon usage of *ypmB*, which is thought to be the ancestral gene on the basis of molecular (IS1541) typing of thirty nonepidemiologically related *ypm*-positive strains of *Y. pseudotuberculosis* (Carnoy and Simonet, 1999), is different from that of *S. aureus*, *S. pyogenes* and *M. arthritidis*. This indicates that the *ypm* genes came from another microbial source (Carnoy et al., 2002). The sequence of the genetic environment of the superantigen-encoding gene showed that *ypm* is not associated with other virulence genes, and that unlike many staphylococcal and streptococcal superantigen genes, it is not located on a mobile genetic element, such as a phage, a transposon or a plasmid. It is now known that the chromosomal region containing *ypm* is the site at which deletion/insertion genetic events occur. The presence of a recombination/phage integration site upstream of the superantigen gene probably contributes to the occurrence of these events (Carnoy et al., 2002). However, it is still not known how *Y. pseudotuberculosis* acquired *ypm*.

Other Putative Virulence Factors (Elisabeth Carniel)

In addition to the well-characterized factors described above, other factors have been implicated to different extents in *Yersinia* pathogenesis, but their role often remains obscure or controversial. A few of them are presented below.

HEAT-STABLE ENTEROTOXINS OF *Y. ENTEROCOLITICA* Three types of heat-stable enterotoxins, designated “YSTa,” “YSTb,” and “YSTc,” have been identified in *Y. enterocolitica* until now.

YSTa Mode of Action The presence of a heat-stable methanol-soluble enterotoxin YST (now YSTa) produced by *Y. enterocolitica* was initially detected in the infant-mouse test (Pai and Mors, 1978; Boyce et al., 1979; Feeley et al., 1979; Okamoto et al., 1980). Its structure and mode of action are similar to those of the heat-stable methanol-soluble toxin STI (for stable toxin I) of enterotoxigenic *E. coli* (Pai and Mors, 1978; Boyce et al., 1979; Feeley et al., 1979; Robins-Browne et al., 1979b). This enterotoxin activates the particulate form of intestinal guanylate

cyclase and induces fluid accumulation by increasing the concentration of cyclic GMP levels within intestinal epithelial cells (Rao et al., 1979; Robins-Browne et al., 1979b; Inoue et al., 1983; Inoue et al., 1984b; Inoue et al., 1986).

Structure The chromosomal *ystA* gene encodes a 71-amino-acid (AA) product (Delor et al., 1990). The mature 30-AA enterotoxin found in supernatants is a processed form obtained after removal of the N-terminal 19-amino acid (AA) signal sequence (pre-domain) and cleavage of the central 22-AA pro-domain during or after secretion (Takao et al., 1984; Takao et al., 1985; Delor et al., 1990). This organization in pre-, pro- and mature YSTa is reminiscent of that of the *E. coli* STI. The conservation of the pre- and pro-domains between *Y. enterocolitica* and *E. coli* is moderate and the size of the mature toxin is much larger in the former (30 AA) than in the latter (18 AA) species (Delor et al., 1990). Heat-stable enterotoxins (STs) produced by various enteric bacteria share a highly conserved sequence formed of 13 AA with 6 Cys residues linked by 3 disulfide bonds. This sequence, which constitutes the toxic domain of the peptide and is highly conserved among heat-stable toxins, is also present in YSTa (Takao et al., 1985; Delor et al., 1990).

Regulation In vitro, maximal synthesis of YSTa occurs at 26°C, during the late phase of growth (Boyce et al., 1979; Amirmozafari and Robertson, 1993) and is due to a transcriptional regulation of *ystA* (Mikulskis et al., 1994; Nakao et al., 1994; Nakao et al., 1995). However, transcription of *ystA* could still be induced at 37°C by increasing osmolarity and pH to the values normally present in the ileum lumen (Mikulskis et al., 1994), suggesting that the enterotoxin may be produced under physiological conditions. Two global regulators, the histone-like negative regulator YmoA (Mikulskis et al., 1994) and the *yrp* (*Yersinia* regulator for pleiotropic phenotype) locus homologous to the *hfq* gene encoding a host factor protein of *E. coli* (Nakao et al., 1994; Nakao et al., 1995), participate in this temperature and growth phase regulation.

Although fresh clinical isolates of *Y. enterocolitica* generally produce YSTa, silencing of *ystA* is frequently observed upon storage in vitro. The two regulators YmoA and Yrp also participate in the switching on and off of *ystA*. YmoA is involved in *ystA* silencing, and a mutation in *ymoA* reactivates the production of YSTa (Cornelis et al., 1991; Mikulskis et al., 1994). By contrast, *yrp* is necessary for *ystA* expression. Various mutations in *yrp* were found in *Y. enterocolitica* strains that had a silent *ystA* gene, and complementation of these strains with an active

yrp locus restored YST production (Nakao et al., 1994; Nakao et al., 1995).

Role in Pathogenicity The role of YSTa in the pathogenesis of *Y. enterocolitica* diarrhea in humans remains controversial. A *Y. enterocolitica* O:3 strain that did not produce YSTa was still capable of producing diarrhea in orally infected mice (Schiemann, 1981a). In a gnotobiotic newborn piglet model, a *Y. enterocolitica* O:3 *yst* mutant remained virulent (Robins-Browne et al., 1985b). Furthermore, no enterotoxin production was detected in feces or intestines of mice, rabbits, or piglets with *Y. enterocolitica*-induced diarrhea (Pai et al., 1980; Schiemann, 1981a; Robins-Browne et al., 1985b). In contrast, in a model of orally infected young rabbits, a *ystA* mutant of *Y. enterocolitica* O:9 lost the ability to cause diarrhea, weight loss, and death of the animals. The mutant was also eliminated more rapidly from the feces than the YSTa-producing parental strain (Delor and Cornelis, 1992).

The demonstration that 100% of pathogenic versus 0% of nonpathogenic *Y. enterocolitica* harbored the *ystA* locus (Delor et al., 1990; Robins-Browne et al., 1993) was also an argument for a role of YSTa in pathogenesis. However, a few strains belonging to the nonpathogenic species *Y. kristensenii* and *Y. intermedia* were also found to possess the *ystA* locus (Delor et al., 1990; Ramamurthy et al., 1997b).

YSTb Investigation of a large number of *Y. enterocolitica* isolates for the presence of the *ystA* locus and the production of an enterotoxigenic activity revealed that some strains did produce an enterotoxin despite the absence of an *ystA* gene (Robins-Browne et al., 1993; Yoshino et al., 1994b). A novel enterotoxin, designated "YSTb," was purified from the supernatant of a *Y. enterocolitica* O:5 strain and characterized. This new toxin was found to be 20-fold more potent in the suckling mouse assay than YSTa (Yoshino et al., 1994b). This higher toxicity was attributed to the substitution of Trp¹⁷ for Asp¹⁷, and of Glu²⁰ for Asp²⁰ (Yoshino et al., 1994b) in YSTb. The amino-acid sequence of the 30-AA mature form of YSTb differed from that of YSTa in the N-terminal part of the peptide (AA 1–17) but was similar in its C-terminal portion (AA 18–30; Yoshino et al., 1994b).

The *ystB* gene was subsequently cloned and found to be 73.5% identical to *ystA*. It had the potential to encode a 71-AA long peptide (Ramamurthy et al., 1997b). Screening of a large number of *Y. enterocolitica* isolates for the presence of *ystB* indicated that this gene is present in 11.8% of isolates, which all belonged to the nonpathogenic group of biotype 1A (Ramamurthy et al., 1997b).

YSTc Another novel heat-stable enterotoxin, designated "YSTc," was identified from an enterotoxigenic *Y. enterocolitica* O:3 strain, which failed to hybridize with *ystA* (Yoshino et al., 1995b). In contrast to YSTa and YSTb, the mature form of YSTc was very long (53 AA), representing the largest molecular size toxin in the family of currently known STs. This secreted peptide was composed of the pro- and mature domain of the polypeptide (Yoshino et al., 1995b). The presence of the pro-domain in the secreted mature toxin suggests that in *Y. enterocolitica*, the proteolytic processing of the pro-domain is not essential for the secretion of YSTc to the extracellular compartment through the outer membrane. The toxic domain in the C-terminal portion of YSTc was well conserved (Yoshino et al., 1995b).

In contrast to YSTa, YSTb is produced in cells grown at 37°C (Yoshino et al., 1995b). YSTc was found to have an enterotoxigenic activity four times superior to those of YSTb and STb of *E. coli*, which had been known as the most potent STs. Therefore, YSTc may be considered as the most potent enterotoxin in the ST family (Yoshino et al., 1995b).

The *ystC* gene is 73.1% and 73.5% identical to *ystA* and *ystB*, respectively (Huang et al., 1997; Ramamurthy et al., 1997b) and encodes a 72-AA product (Huang et al., 1997). Screening of a large number of *Y. enterocolitica* isolates for the presence of *ystC* indicated that this gene is present in a very low number of isolates (1%) belonging either to the pathogenic or the nonpathogenic group (Ramamurthy et al., 1997b).

Conclusion To date, three different heat-stable enterotoxins have been identified in *Y. enterocolitica*. The high degree of identity between these three enterotoxins indicates that they should not be considered as different STs but as different subtypes of YST (Yoshino et al., 1994b). The fact that none of the *Y. enterocolitica* strains tested hybridized with more than one probe (Ramamurthy et al., 1997b) may indicate a mutual exclusion of these three gene subtypes in *Y. enterocolitica*. Finally, the existence of pathogenic (and therefore diarrheagenic) strains that do not harbor any of the three known enterotoxigenic genes (Ramamurthy et al., 1997b) suggests that additional, yet unidentified, enterotoxins may be produced by *Y. enterocolitica*.

FIMBRIAE Pathogenic *Yersinia* synthesize a fibrillar structure at their surface, designated "Myf" (mucoid *Yersinia* factor) in *Y. enterocolitica* and pH6 antigen (or Psa) in *Y. pseudotuberculosis* and *Y. pestis*. Although these two fimbriae may not necessarily play the same role and seem to have diverged more than other virulence factors

during evolution, they share some common epitopes. They are produced in the same environmental conditions, and their chromosomal loci display a similar genetic organization and some degree of nucleotide identity (Iriarte et al., 1993; Lindler and Tall, 1993; Iriarte and Cornelis, 1995; Leiva et al., 1995).

Properties of Myf in *Y. enterocolitica* The Myf antigen was originally described as a 24-kDa protein loosely associated with the bacterial membrane (Diaz et al., 1985). Synthesis of this antigen was obtained only when the bacteria were grown on solid media at 37°C, in the presence of a metabolizable sugar. Immunogold labeling subsequently revealed that Myf forms a fibrillar structure extending 2 µm from the cell surface (Iriarte et al., 1993).

Although never demonstrated, the role of Myf in *Y. enterocolitica* pathogenesis was suggested by the observations that only pathogenic serotypes of *Y. enterocolitica* produced these fimbriae (Diaz et al., 1985; Toyos et al., 1986) and harbored the pilin subunit-encoding gene *myfA*. However, the presence of the *myfA* locus was recently detected in some *Y. enterocolitica* strains of biotype 1A (Grant et al., 1998), which are conventionally considered as nonpathogenic.

Properties of pH6 Antigen in *Y. pseudotuberculosis* and *Y. pestis* The pH6 antigen (Ag) received its name following the observation that a specific antigenic surface component was produced by various strains of *Y. pestis* after incubation at 37°C and at pH6 (Ben-Efraim et al., 1961). This antigen was subsequently identified in *Y. pseudotuberculosis* (Ben-Efraim and Bichowsky-Slomnicki, 1964; Lindler and Tall, 1993) and found to be highly conserved, both genetically and immunologically, between the two species (Lindler and Tall, 1993). However, while all strains of *Y. pestis* produced pH6 Ag, only some isolates of *Y. pseudotuberculosis* appeared to do so (Ben-Efraim and Bichowsky-Slomnicki, 1964; Lindler and Tall, 1993).

Electron microscopy and immunogold labeling demonstrated that pH6 Ag forms fibrillar organelles that protrude from the cell surface as subtle, fine, singular strands (ca. 4 nm in diameter), as multistranded bundles, or as large aggregates in *Y. pestis*, *Y. pseudotuberculosis* and *E. coli* clones carrying the *psa* locus (Lindler and Tall, 1993).

Crude extracts of *Y. pestis* pH6 Ag were initially found to be cytotoxic for monocytes, to agglutinate erythrocytes, and to induce inflammatory reactions of the skin (Bichowsky-Slomnicki and Ben-Efraim, 1963). The hemagglutination property of the *Y. pseudotuberculosis* pH6 Ag was also demonstrated (Yang

et al., 1996; Yang and Isberg, 1997). The protein appears to possess several other properties. It binds to the Fc portion of human immunoglobulin (Ig)G (but not that of rabbit, mouse, and sheep IgG) and can thus be considered as a bacterial Fc receptor (Zav'yalov et al., 1996). It mediates thermoinducible adhesion of *Y. pseudotuberculosis* to cultured epithelial cells (Yang et al., 1996). It binds the β1-linked galactosyl residues in glycosphingolipids (Payne et al., 1998b).

Several pieces of evidence indicate a role for pH6 Ag in *Y. pestis* pathogenesis: 1) antibodies against pH6 Ag were found in the sera of rabbits infected with various *Y. pestis* isolates (Ben-Efraim et al., 1961), 2) *Y. pestis* cells recovered from the spleen or liver of infected mice expressed the antigen at their surface (Ben-Efraim et al., 1961), 3) the rate of mouse mortality was higher during the first 4 days postinfection when the animals were infected with pH6 Ag-expressing cells (grown at pH6) than with pH6 Ag-nonexpressing cells (grown at pH7; Ben-Efraim et al., 1961), 4) *Y. pestis* associated with a murine macrophage-like cell line expressed pH6 Ag in an intracellular acidification-dependent manner (Lindler and Tall, 1993), and 5) mutation in the *psa* locus (*psaA* or *psaE*) resulted in a ≥100-fold increase in the LD₅₀ for mice infected retro-orbitally (Lindler et al., 1990).

Genetic Organization of the *myf* and *psa* Loci The genetic organizations of the Myf and pH6 Ag systems are very similar. The different components of these two systems and their putative locations and functions are summarized in Table 34.

Structural Components *PsaA/MyfA* encodes the major 21-kDa subunit of the fimbriae, which are assembled at the bacterial surface by the transport and assembly machinery composed of *PsaB/MyfB* and *PsaC/MyfC* (Iriarte et al., 1993; Yang and Isberg, 1997). The Myf and pH6 Ag display homology with the corresponding components of the Pap system of *E. coli* and partly with the pFra-encoded Caf system of *Y. pestis* (Iriarte et al., 1993; Lindler and Tall, 1993).

Regulation The *myf* (*psa*) locus is composed of two operons: *myfEF* (*psaEF*) and *myfABC* (*psaABC*). Expression of *myfABC* (*psaABC*) is regulated at the transcriptional level by temperature and pH, and requires the upstream activators *myfE/psaE* and *myfF/psaF* (Iriarte et al., 1993; Price et al., 1995; Yang and Isberg, 1997). However, *psaEF*, itself, is not regulated by pH or temperature (Lindler et al., 1990) but is constitutively expressed (Yang et al., 1996). Although

Table 34. Correspondence between the different components of the Myf and pH6 Ag systems.

<i>Y. enterocolitica</i>	<i>Y. pestis</i> <i>Y. pseudotuberculosis</i>	Putative location	Putative function
MyfF	PsaF	Inner membrane and periplasm	Activator
MyfE	PsaE	Cytoplasm, inner membrane, and periplasm	Activator
MyfA	PsaA	Surface	Subunits of fimbriae
MyfB	PsaB	Periplasm	Chaperone
MyfC	PsaC	Outer membrane	Transport and assembly

a temperature of 37°C is required for full expression of *psaABC*, pH is the initial environmental stimulus essential for expression of *psaA* (Price et al., 1995). The *myfABC* operon can be transcribed from either a classical $\sigma 70$ or a $\sigma 28$ promoter (Iriarte and Cornelis, 1995).

PsaE has an N-terminal cytoplasmic domain and a periplasmic C-terminal domain, and shares similarities with transcriptional regulators found in two-component systems (Yang and Isberg, 1997). PsaF/MyfF is presumably involved in transduction of the signal triggering transcription of *myfABC*. The predominant localization of PsaF/MyfF in the periplasm strikingly resembles that of ToxS, a protein involved in regulation of Tcp pilus production in *Vibrio cholerae* (Iriarte and Cornelis, 1995) and suggests that MyfF may be part of a cascade of regulation. It is thus possible that the two regulators MyfE/PsaE and MyfF/PsaF interact with each other in the periplasm and function together to sense environmental cues such as pH and temperature (Iriarte and Cornelis, 1995; Yang and Isberg, 1997).

IRON UPTAKE SYSTEMS The ability to capture iron in vivo through the HPI-borne yersiniabactin system is a key determinant that differentiates high- and low-pathogenicity *Yersinia* strains. In addition to this potent iron-acquisition system, *Yersinia* spp. have developed other strategies to acquire this important metal. The iron acquisition systems other than yersiniabactin are presented below.

Role of Iron in the Pathogenesis of Enteropathogenic *Yersinia* Iron serves as a cofactor in a number of enzymatic and metabolic pathways and represents an essential growth factor for almost all bacteria except certain lactobacilli and *Borrelia burgdorferi* (Posey and Gherardini, 2000). In mammals, this metal is bound to eukaryotic proteins (hemoglobin, ferritin, transferrin and lactoferrin), which maintain a level of free iron exceedingly too low (10^{-18} M) to sustain bacterial growth. Among bacterial pathogens, the successful establishment of disease depends

on the ability of the invading organism to acquire iron. Microbial pathogens must therefore adapt to the iron-restricted milieu found in vivo and develop high-affinity iron transport systems called "siderophores."

Low-pathogenicity strains of *Y. enterocolitica* (biotypes 2 and 4) and *Y. pseudotuberculosis* serotypes II, IV and V do not produce their own siderophore and are usually restricted to the intestinal tract. However, these bacteria can cause systemic infections if a source of iron becomes available in vivo. Clinical case descriptions of disseminated infections due to low-pathogenicity *Yersinia* in iron-overloaded patients are numerous in the literature. This iron-overload status responsible for disseminating *Yersinia* infections had different origins: oral overdose of iron (Robins-Browne et al., 1979a; Soriano et al., 1981; Melby et al., 1982; Mofenson et al., 1987); iron therapy (Leighton and MacSween, 1987; Fakir et al., 1995); hemodialysis (Boelaert et al., 1987) and long-term transfusion therapy (Schuchmann et al., 1997); and underlying diseases that increase directly or indirectly (through blood transfusions) the iron burden of the patients:

- 1) hypersideremia without any known etiology (Sibilia et al., 1991),
- 2) primary hemochromatosis (Jacquenod et al., 1984; M'Rad et al., 1988; Shibuya et al., 1988; Merrien et al., 1991; Vadillo et al., 1994; Collazo et al., 1995; Piroth et al., 1997; Höpfner et al., 2001),
- 3) thalassemia (Blum et al., 1970; Hewstone and Davidson, 1972; Seigneurin et al., 1972; Rabson et al., 1975; Bouza et al., 1980; Hambourg et al., 1980; Soriano et al., 1981; Adamkiewicz et al., 1998),
- 4) autoimmune hemolytic anemia (Guez et al., 1987), and
- 5) liver diseases (Marlon et al., 1971; Seigneurin et al., 1972; Rabson et al., 1975; Imhoof and Auckenthaler, 1980; Soriano et al., 1981; Jacquenod et al., 1984; Merrien et al., 1991).

The role of iron in *Yersinia* pathogenicity was also demonstrated in the mouse experimental

model of infection. Low-pathogenicity *Y. enterocolitica* strains, which are naturally nonlethal for mice, gained this lethal power when exogenous iron was administered to the animals (Robins-Browne and Prpic, 1985a; Smith et al., 1981). The suppressive effect of this metal on the host immune response may partly account for the enhanced bacterial pathogenicity. Nonetheless, iron appears to play a crucial role in *Yersinia* pathogenesis.

Utilization of Exogenous Siderophores Several siderophores that are not synthesized by *Y. enterocolitica* and *Y. pseudotuberculosis* can still be used as a source of iron when they are supplied in the growth medium (Perry and Brubaker, 1979; Brock and Ng, 1983; Brock et al., 1988; Rabsch and Winkelmann, 1991; Bäumler et al., 1993; Table 35).

One of the clinically most important exogenous siderophores is deferoxamine B, a licensed therapeutic substance (Desferal®) commonly used to treat patients with iron-overload (thalassemia, hemodialysis, etc.). This hydroxamate-type siderophore, naturally produced by *Streptomyces pilosus* and by various enterobacteriaceae, can be used by low-pathogenicity yersiniae for capturing iron, thus enhancing their ability to disseminate in a mouse host (Robins-Browne and Prpic, 1985a). Clinical reports of deferoxamine-treated patients that developed fulminant *Y. enterocolitica*-disseminated infections are numerous (Kiffer et al., 1975; Butzler et al., 1978; Di Palma et al., 1982; Roche et al., 1982; Robins-Browne and Prpic, 1983; Aristegui et al., 1985; Boyce et al., 1985; Waterlot and Vanherweghem, 1985; Gallant et al., 1986; Trallero et al., 1986; Francois et al., 1987; Warren, 1987; Hoen et al., 1988; Chirio et al., 1990; Cianciulli et al., 1990; Abcarian and Demas, 1991; Mazzoleni et al., 1991; Pacifico et al., 1991; Hoe et al., 1994; Cherchi et al., 1995; Paitel et al., 1995; Adamkiewicz et al., 1998). This virulence enhancing effect of deferoxamine has at least two causes. One is the synthesis by *Y. enterocolitica*

of the outer-membrane protein FoxA that acts as a receptor for the exogenous siderophore (Bäumler and Hantke, 1992). The other is the modulation/abolition of the action of specific and nonspecific immune cells and the inhibition of cytokine production by macrophages, leading to partial immunosuppression of the host (Autenrieth et al., 1991; Autenrieth et al., 1994b; Autenrieth et al., 1995). Thus, low-pathogenicity *Y. enterocolitica* strains usually restricted to the digestive tract can use deferoxamine to obtain the limiting iron molecules and benefit from the induced-immune deficiency to disseminate in their host and cause systemic infections.

To utilize exogenous siderophores, pathogenic *Yersinia* need to express the specific receptors on their surface and/or the appropriate transporters across their two membranes. Several of these receptors have been identified in *Yersinia* (Table 35). They all possess a TonB box and their synthesis is induced under iron-stress conditions (Bäumler and Hantke, 1992; Koebnik et al., 1993a; Koebnik et al., 1993b).

Analysis of the membrane topology of the deferoxamine receptor FoxA indicates that this protein forms a barrel consisting of 32 trans-membrane β -pleated sheets (Bäumler and Hantke, 1992; Bäumler et al., 1993). While FoxA displays an exclusive specificity for deferoxamine B, the ferrichrome receptor FcuA can transport almost all ferrichrome derivatives with equal efficiency (Koebnik et al., 1993b). Both FoxA and FcuA carry a Fur box, suggesting that they are both negatively regulated by this protein in the presence of iron (Bäumler and Hantke, 1992; Koebnik et al., 1993b). A mutation in *foxA* or *fcuA* does not alter the virulence of *Y. enterocolitica*.

The enterochelin receptor FepA has been recognized by monoclonal antibodies raised against *E. coli* FepA as a 90-kDa protein in *Y. enterocolitica* membrane extracts (Rutz et al., 1991). Curiously, in some *Y. enterocolitica* strains (serotype O:8 and O:20), the *fepA* gene contains a frameshift mutation that leads to a truncated

peptide, while in other strains (serotype O:13 and O:5), a 31-bp insertion leads to the restoration of a single ORF (Schubert et al., 1999a). Genes involved in enterochelin transport (*fepDGC*) and in the release of iron from enterochelin (*fes*) in the cytosol are present and functional in *Y. enterocolitica* O:8, while those involved in enterochelin biosynthesis (*ent*) are absent from the bacterial genome (Schubert et al., 1999a).

Iron Uptake from Heme-Proteins Another pathway used by *Yersinia* to capture iron is to utilize the iron molecules bound to heme-proteins. A locus involved in hemin uptake (*hem*) has been characterized in *Y. enterocolitica* (Stojiljkovic and Hantke, 1992; Stojiljkovic and Hantke, 1994). This locus is homologous to the hemin locus uptake (*hmu*) of *Y. pestis* (86–93% AA identity; Thompson et al., 1999) and allows the utilization of a wide range of heme-proteins as sources of iron (Bracken et al., 1999). In addition to iron, some heme-proteins may also be used as a source of porphyrin by *Yersinia* (Stojiljkovic and Hantke, 1992).

The *hem* locus is composed of at least six genes forming two operons: *hemPR* and *hemSTUV*, and is iron- and Fur-regulated (Stojiljkovic and Hantke, 1994). The location and putative functions of the products of this locus are listed in Table 36. HemR is the TonB-dependent iron-regulated surface receptor for heme. Its membrane topology probably consists in 22 trans-membrane β -strands and 11 surface-exposed loops (Bracken et al., 1999). Two histidine residues (His¹²⁸ and His⁴⁶¹) are thought to participate in the transport of heme through the HemR pore (Bracken et al., 1999). A model has been proposed in which the HemTUV complex transports hemin into the bacterial cytoplasm where it is degraded by HemS, thereby liberating the iron molecules and preventing the toxic effect of heme (Stojiljkovic and Hantke, 1994). The HemSTUV system of heme transport across the inner membrane is similar to the siderophore-uptake systems. HemP is not essential for hemin-porphyrin or hemin-iron utilization (Stojiljkovic and Hantke, 1994).

Interestingly, the *hem* locus is located close to the *foxA* gene that codes for the ferrioxamine

receptor, forming a chromosomal “iron island.” Since a *hemR* mutant strain of *Y. enterocolitica* retains its pathogenicity upon intravenous injection, heme capture does not seem to be crucial for bacterial survival in vivo (Stojiljkovic and Hantke, 1992).

The heme-uptake system has not yet been studied in *Y. pseudotuberculosis*. However, the strong hybridization signal obtained with an *hmu* probe suggests that a similar system exists in this species (Thompson et al., 1999).

Siderophore-independent Iron Transport System

A TonB-independent ferric uptake system (Yfu) is present in pathogenic and nonpathogenic *Yersinia* spp. The Yfu system of *Y. enterocolitica* shows high AA identity (76.8–83.7%) to its *Y. pestis* homologue and also to the *Serratia marcescens* system (Saken et al., 2000; Gong et al., 2001). The *Y. enterocolitica* *yfu* locus is composed of four genes (*yfuA*, *yfuB*, *yfuC* and *yfuD*). A putative Fur binding site is found in the promoter region of *yfuA*. On the basis of similarities with other known proteins, YfuA (33.8 kDa in its mature form) is expected to be a periplasmic iron-binding protein, YfuB (56.5 kDa) is an inner-membrane permease containing a DNA binding site, YfuC (37.9 kDa) is probably an ATP-binding ABC transporter, and YfuD (22.8 kDa) is also probably an inner membrane permease (Saken et al., 2000). The function of the *Y. enterocolitica* Yfu system is supposed to be restricted, as is the function of the iron transport systems of other bacteria, to iron transport from the periplasm to the inner compartment of the cell and does not require a membrane receptor. Mutation in YfuB impairs neither the in vitro iron-utilization nor the virulence of *Y. enterocolitica* 1B/O:8 (Saken et al., 2000).

Immunology (Ingo Autenrieth)

Basic Considerations: Host Defense Against Extracellular and Intracellular Pathogens

As enteric *Yersinia* spp. are pathogenic for man as well as for rodents, data available on host responses against *Y. enterocolitica* and *Y.*

Table 36. The heme-uptake system of *Y. enterocolitica*.

Protein	Molecular mass (kDa)	Location	Putative function
HemP	6.5	UN	UN
HemR	78	Outer membrane	Heme receptor
HemS	39.2?	Cytoplasm	Heme-degrading enzyme
HemT	27	Periplasm	Heme-binding transport protein
HemU	35	Cytoplasmic membrane	Permease
HemV	31	Cytoplasmic membrane	Heme-specific ATPase

Abbreviation: UN, unknown.

pseudotuberculosis from both clinical studies in man and experimental animal infection models are considerable. Although experimental data from animals cannot be simply extrapolated to human yersiniosis, it is important to note that most, if not all, features of human yersiniosis (including enteritis and reactive arthritis) can be reproduced in various animal models including mice, rats and rabbits (Heesemann et al., 1993a). Therefore, it is conceivable that the features observed in these animal models may be relevant to the pathogenesis of human yersiniosis.

Immunity against enteric *Yersinia* spp. is based on innate and acquired host defense mechanisms. Most of the data available on this subject results from murine studies with *Y. enterocolitica*. Therefore, most of the data included herein may hold true for infections with *Y. enterocolitica* rather than for those caused by *Y. pseudotuberculosis*. This is important as *Y. enterocolitica* and *Y. pseudotuberculosis* may differ in their ability to induce immune responses. While *Y. enterocolitica* appears to be located exclusively extracellularly in host tissues, this is not yet completely established for *Y. pseudotuberculosis*. In fact, some of the data even imply that *Y. pseudotuberculosis* might be located both extra- and intracellularly in host tissues. This is an important basic consideration as immunity to microorganisms depends on their location in host tissues (Allen and Maizels, 1997; Autenrieth et al., 1999). Thus, extracellular pathogens are continuously exposed to components of the host defense such as complement or phagocytic cells as well as antibodies, while intracellular pathogens may evade these host defense systems. Therefore, it was believed that host responses and immunity to extracellular pathogens is rather trivial and a matter of polymorphonuclear leukocytes (PMNs), complement, and antibodies. However, expression of virulence factors by *Yersinia* spp. (e.g., Yops and YadA) enable *Yersinia* spp. to evade the innate host defense mechanisms including phagocytosis by PMNs and macrophages or complement attack. In consequence, mechanisms including helper (CD_4^+) and cytotoxic (CD_8^+) T cell responses, particularly γ -interferon-producing CD_4 T-helper 1 (Th1) cells, in cooperation with activated macrophages, are required to control *Yersinia* infection. Such host responses are considered as classical host defense mechanisms against (facultative) intracellular pathogens such as *Leishmania*, *Toxoplasma*, *Listeria*, *Mycobacteria* and *Salmonella* (Allen and Maizels, 1997). However, apart from *Yersinia*, other extracellular pathogens such as *Bacteroides* spp. or *Candida albicans* are also controlled by Th1-dependent host responses indicating that the Th1-Th2 paradigm may be of limited value. Moreover, recent work provided

further evidence that the classical segregation of host defense components appears to oversimplify their relevance to the control of intra- and extracellular pathogens, e.g., antibodies might also play a role in neutralizing intracellular bacteria and protecting against the intracellular pathogen *Listeria monocytogenes* (Edelson and Unanue, 2001).

Host Defense Against *Yersinia* spp. at Mucosal Sites

Enteric *Yersinia* spp. are enteroinvasive pathogens. However, they cannot invade polarized intestinal epithelial cells from their apical side and therefore cannot simply invade the intestinal epithelial barrier (Coconnier et al., 1994; Schulte et al., 1998). Rather, they are taken up by M cells, which occur within the follicle-associated epithelium of the Peyer's patches (Grutzkau et al., 1990; Autenrieth et al., 1996b; F. Physiopathology). The M cells are specialized in that they take up particles from the intestinal lumen and transport these particles across the intestinal epithelium barrier. By this means, immune responses in the mucosa-associated lymphoid tissue are initiated, as the Peyer's patches are important components of the afferent limb of this system. Whether like in *Salmonella* infections (Vazquez-Torres et al., 1999) other cell types (e.g., CD_{18} -expressing phagocytes or dendritic cells) are involved in invasion/uptake of *Yersinia* is unknown.

Recently, it was demonstrated in mice and human intestinal epithelial M-like cell lines that M cells, in contrast to enterocytes, expose β_1 integrins at their apical ("luminal") surface, which may bind to the *Yersinia* invasin protein (Clark et al., 1998; Schulte et al., 2000). This interaction leads to the transport of *Yersinia* across the epithelium. This strategy of entry is common in enteric pathogens including *Salmonella* spp. and *Shigella* spp. (Siebers and Finlay, 1996; Jepson and Clark, 1998). However, the invasion strategy of pathogens via M cells is a paradox, as antigen sampling by M cells is an important event for initiating mucosal immunity. In fact, the exploitation of M cells by pathogens stimulates the afferent mucosal immune system which is represented by the Peyer's patches. Thus, entry of enteric *Yersinia* spp. by this route is an ambiguous process. On the one hand, *Yersinia* may use the structure of the mucosal immune system for invasion of host tissue, and most likely for subsequent dissemination. On the other hand, the mucosal immune system is stimulated upon entry of *Yersinia*, and thereby host immune responses are triggered that, in most cases, will eliminate the pathogen.

One day after M cell invasion by *Y. enterocolitica*, small microabscesses consisting of PMNs

and extracellularly located *Yersinia* can be detected in Peyer's patch tissue (Hanski et al., 1989; Autenrieth et al., 1996b). In *Y. pseudotuberculosis*, granulomatous lesions can be observed, and the location (intra- versus extracellular) of *Y. pseudotuberculosis* is less clear (Physiopathology). The type of inflammatory responses induced in Peyer's patches can be considered as a net effect resulting from two contrary events: *Yersinia* spp. obviously trigger the recruitment of inflammatory cells such as PMNs which are normally absent from Peyer's patches. This could be a result of the function of *Yersinia* invasin protein. Recent work demonstrated that invasin, via binding to host cell $\beta 1$ integrins, can trigger activation of proteins of the Rel family, e.g., nuclear factor kappa B (NF- κ B) in epithelial cells (and macrophages) which leads to expression of various genes such as interleukin (IL)-8, granulocyte macrophage-colony stimulating factor (GM-CSF), and monocyte chemoattractant protein (MCP)-1 (Kampik et al., 2000; Schulte et al., 2000). These cytokines, particularly the chemokine IL-8, are proinflammatory cytokines and may cause the recruitment of PMNs. It is unclear whether and how other factors of *Yersinia* such as LPS (via binding to toll-like receptors [TLRs]) or YadA, Myf, etc. (which may interact with the surface of the host cells) contribute to the signaling for proinflammatory cytokine gene expression.

On the other hand, translocation of YopP/J via the type III secretion apparatus may suppress expression of proinflammatory genes via inhibition of NF- κ B activation and may induce apoptosis in macrophages (Monack et al., 1997; Palmer et al., 1998; Ruckdeschel et al., 1998; Schesser et al., 1998). Recent work demonstrated direct evidence that YopP/J may account for such an effect in mesenteric lymph nodes and spleen in an experimental mouse infection model (Monack et al., 1998). This may also be important for a possible role of IL-1 in *Yersinia* infections. IL-1 production is also triggered by invasin-mediated NF- κ B activation (Kampik et al., 2000). However, in contrast to IL-8, GM-CSF, or MCP-1, IL-1 is not released by the host cells. In *Shigella* infection, it was shown that IL-1 may be passively released by macrophages upon induction of apoptosis of the macrophages by *Shigella* (Sansone et al., 1995), and subsequently, IL-1 might augment the inflammatory host responses. It is conceivable that such a scenario might also occur in *Yersinia* infection.

Taken together, present data suggest that M cells and epithelial cells may be among the first cells encountered by yersiniae. Epithelial cells can produce inflammatory cytokines by which they signal to the host immune system the presence of pathogenic microorganisms. Therefore,

they have been called the "watchdogs for the natural immune system" (Eckmann et al., 1995). At present, it is not known whether M cells may also be capable of producing cytokines upon interaction with microorganisms. *Yersinia* might trigger the cytokine responses by binding to $\beta 1$ integrins exposed at the basolateral surface of enterocytes. *Yersinia* may also elicit cytokine production causing proinflammatory cell reactions in the "pocket" adjacent to the basolateral side of M cells, where macrophages and lymphocytes are located.

Histological and immunohistological analyses suggest that innate host defense mechanisms including PMNs and macrophages are involved in control of *Yersinia* in Peyer's patches. Experimental approaches including the administration of neutralizing antibodies against adhesion molecules into mice prior to *Yersinia* infection showed that the adhesion molecules VLA-4 ($\alpha 4\beta 1$ integrin, expressed on T cells, B cells, monocytes and involved in cell trafficking to sites of inflammation by interaction with VCAM-1 on endothelial cells) and Mac-1 (amb2 integrin, complement receptor 3 expressed on phagocytes and involved in binding and phagocytosis of pathogens and cell trafficking by binding to the ICAM-1 expressed on endothelial cells) are involved and play a protective role in the Peyer's patches (Autenrieth et al., 1996b). Thus, blocking of these host defense components by administration of specific antibodies to mice reduced phagocytosis of yersiniae and caused increased bacterial numbers in the tissue, which prevented clearance of *Y. enterocolitica* from Peyer's patches and led to fatal infection courses.

In addition the cytokines TNF- α , IL-12, IL-18 and IFN- γ have been shown to be involved during mucosal infection (Autenrieth et al., 1996b; Bohn and Autenrieth, 1996; Bohn et al., 1998b; Hein, 2000). Thus, by means of neutralizing antibodies in mice deficient for cytokines or cytokine receptors, the protective role of these cytokines has been shown. However, it is not yet established to what extent and which of the cells in the Peyer's patches may produce these cytokines in the early phase of the *Yersinia* infection.

The role of complement in yersiniosis has been demonstrated by in vitro experiments. Thus, particularly YadA is involved in mediating resistance to complement and defensin lysis (Balligand et al., 1985; Pilz et al., 1992; Visser et al., 1996). As YadA is essential for survival of *Yersinia* in host tissue—and therefore is expressed in vivo (Autenrieth et al., 1996b)—it appears unlikely that the complement system, which obviously is subverted by virulence factors expressed by *Yersinia*, is actually involved in host defense against this pathogen. In keeping with this hypothesis, work in an experimental *Yersinia*

rat infection model showed that decompensation of rats had no effect on the bacterial numbers in infected organs, suggesting that the complement system has no protective role in *Yersinia* infections (Gaede et al., 1995b). Nevertheless, in the rat infection model, complement is important for reactive arthritis triggered by *Yersinia* spp. (Gaede and Heesemann, 1995a). *Yersinia*-triggered reactive arthritis occurs usually after resolution of the infection and is considered as the result of an immunopathological host reaction. Interestingly, in the experimental rat model of reactive arthritis, decompensation by cobra venom factor suppressed *Yersinia*-induced reactive arthritis in Lewis rats. Whether this is due to reduction of the inflammatory reaction mediated by immune complexes composed of killed or degraded yersiniae precipitated in synovial tissue remains to be elucidated by further analysis.

Secretory IgA (sIgA) antibodies are secreted onto mucosal surfaces and may prevent invasion of pathogens. In fact, by means of a hybridoma tumor model, the transfer of hybridoma cells secreting monoclonal anti-*Salmonella* LPS antibodies prevented salmonellosis in mice (Michetti et al., 1992). In patients with yersiniosis, IgA antibodies directed against various antigens, including the Yop proteins, can usually be detected in serum, and in fact, is of considerable diagnostic value. The immunobiological role of sIgA antibodies in host defense against enteric *Yersinia* spp. is not yet established. Oral inoculation of recombinant *Y. enterocolitica* expressing a YopH-CtxB hybrid protein induced sIgA antibodies against the cholera toxin B subunit in the intestinal and respiratory tract and conferred protection of mice against a cholera toxin challenge (Van Damme et al., 1992). Moreover, preliminary work showed that sIgA is produced upon *Y. enterocolitica* O:8 wildtype infection in mice (C. Bielfeldt et al., unpublished observation). However, it is not clear whether sIgA antibodies might prevent invasion of the intestine by yersiniae or might contribute to control of the yersiniae or to modulation of the course of the infection. It might also be conceivable that the occurrence of a certain level of IgA antibodies in *Yersinia* infections might reflect an inappropriate T cell response including the development of strong Th2 responses resulting in chronic yersiniosis and possibly reactive arthritis rather than in control of the pathogen.

After replication in Peyer's patches, enteric *Yersinia* spp. disseminate via the lymphatics and possibly via the blood stream to the mesenteric lymph nodes, spleen, liver, lungs and peripheral lymph nodes (Physiopathology). The typical tropism for these organs is unclear and may reflect the tropism via adherence or invasion of *Yersinia*

for certain types of host cells or tissues. Preliminary data suggest that phagocytes expressing the Mac-1 molecule may be involved in the dissemination process of yersiniae (Autenrieth et al., 1996b). Likewise, in *Salmonella* infection CD18⁺ host cells, possibly dendritic cells, have been demonstrated to be involved in intestinal translocation and dissemination as well as in induction of immune responses (Vazquez-Torres et al., 1999). Recent work demonstrated that *Y. enterocolitica* can be internalized by dendritic cells (DCs) and does not induce necrosis or apoptosis in these cells, but affects maturation of DCs (Schoppet et al., 2000). In fact, upon interaction with DCs, *Yersinia* modulates dendritic cell function including upregulation of CD83 and CD86 and a transient downregulation of MHC class II molecule expression resulting in decreased ability of dendritic cells to promote T cell proliferation (Schoppet et al., 2000). As T cell responses are crucial for resolution of *Yersinia* infection, modulation of DC functions might be a strategy to evade acquired immune responses by *Y. enterocolitica*. The role of DCs in yersiniosis should be further defined inasmuch as DCs are important sensors of infection and central in the development of immune responses against pathogens (Reis e Sousa, 2001).

Acquired Immunity to *Yersinia* spp.

Almost ten years ago, first direct evidence for a role of T cells in control of infection with enteric *Yersinia* spp. was reported (Autenrieth et al., 1992b). Today it is well established that *Yersinia* infection leads to strong T cell responses including CD4 and CD8 T cells, and that the T cells are involved in control of *Yersinia* (Autenrieth et al., 1992b; Autenrieth et al., 1993; Bohn and Autenrieth, 1996; Noll and Autenrieth, 1996; Bohn et al., 1998a). In fact, mice deficient in T cells are unable to control the pathogen and therefore develop chronic progressive and fatal infection. Consistently, the adoptive transfer of *Yersinia*-specific CD4⁺ or CD8⁺ T cells mediates resistance against a normally lethal challenge of *Yersinia*. As the protective CD4 or CD8 T cells produced cytokines such as IFN- γ and IL-2, but not IL-4 or IL-10, it can be concluded that Th1 or TC1 cells (cytotoxic T cells that secrete γ -interferon) are protective in yersiniosis.

Th1 cells produce predominantly IFN- γ , and it is established that IFN- γ may activate macrophages, which in turn might be able to kill a pathogen. In fact, T cell-activated macrophages are likely to be the most important effector cells in yersiniosis. Interestingly, in these cells, *Yersinia* may induce apoptosis via translocation of YopP/J (Monack et al., 1997; Palmer et al., 1998; Ruckdeschel et al., 1998; Schesser et al., 1998).

Therefore, we can speculate that enteric *Yersinia* spp. can evade innate immunity including phagocytosis by PMNs and macrophages and possibly also, at least to some extent, acquired immunity in which macrophages are important mediators of effector functions as well as required for antigen presentation. By translocation of YopH into the cytosol of T cells or B cells, *Yersinia* may furthermore impair calcium fluxes in these cells and their ability to be activated through their antigen receptors (Yao et al., 1999). Thus, *Yersinia* may impair the development of acquired immunity. Nevertheless, as *Yersinia* infection is usually a self-limited disease, these immune evasion strategies are only partially successful, and at the end, *Yersinia* are obviously not capable of efficiently evading acquired immunity including phagocytosis and killing by most likely T cell-activated macrophages.

The role of cytokines in yersiniosis has been extensively studied in mice by comparison of mouse strains that are relatively susceptible (e.g., BALB/c) or resistant (e.g., C57BL/6) to *Yersinia* infection. One reason for this differential susceptibility of mice is their different ability to mount Th1 responses upon *Yersinia* infection including production of IFN- γ (Autenrieth et al., 1994a; Bohn et al., 1994). *Yersinia*-resistant C57BL/6 mice can be rendered *Yersinia*-susceptible by in vivo neutralizing IFN- γ with monoclonal antibodies (Autenrieth et al., 1994a). Vice versa, *Yersinia*-susceptible BALB/c mice can be rendered resistant by treatment with IFN- γ . In keeping with these results, it was found that administration of neutralizing anti-IL-4 antibodies rendered BALB/c mice resistant against *Yersinia* infection. More recent work with cytokine- or cytokine receptor-deficient mice clearly demonstrated that the cytokines TNF- α , IL-12, IL-18 and IFN- γ , and the transcription factor interferon consensus-sequence-binding protein are all essential for control of *Yersinia* infection (Bohn and Autenrieth, 1996; Bohn et al., 1998b; Hein et al., 2000). Although recent work suggested that in a very particular experimental setting including very high numbers of *Y. enterocolitica* in intravenous infections, 55-kDa tumor necrosis factor receptor (TNFRp55)-mediated mechanisms might be eventually detrimental to the host (Zhao et al., 2000). TNFRp55-dependent mechanisms in general are crucial for overcoming yersiniosis (Autenrieth and Heesemann, 1992a; Autenrieth et al., 1996b; Bohn et al., 1998b).

Epitope mapping of murine protective *Yersinia*-reactive T cell clones showed that a heat shock protein (HSP)60 of *Y. enterocolitica* is an immunodominant and protective antigen for CD₄ T cells and presented by MHC class II molecules (Noll et al., 1994; Noll and Autenrieth,

1996). Interestingly, the epitopes recognized by the T cells do not share significant homology to the corresponding mammalian HSP60 sequences. Recently, studies in humans confirmed these observations and demonstrated that *Yersinia* HSP60 is an immunodominant antigen for CD₄ and CD₈ T cells in reactive arthritis in humans (Mertz et al., 2000). A 12-mer core epitope (amino acids [aa] 322–333) of aa 319–342 peptide was recognized by T cell clones from one patient in the context of different human leukocyte antigen (HLA)-DR alleles suggesting that these findings might be relevant to other human individuals. Interestingly, although IFN- γ was the most abundant cytokine secreted by these human T cell clones, some clones also secreted considerable amounts of IL-10. As IL-10 is an inhibitory cytokine, *Yersinia*-HSP60-triggered IL-10 secretion might promote bacterial persistence in chronic infections. Like in mice, all T cell clones reactive with *Yersinia* HSP60 did not crossreact with human HSP60. These results argue against the hypothesis that T cell responses against shared epitopes of HSPs might be involved in the pathogenesis of reactive arthritis after *Yersinia* infection. Whether *Yersinia* heat shock proteins might be released and stimulate innate immune responses by engaging toll-like receptors (TLRs; Wagner, 2001) is unclear. In summary, we can conclude that CD₄ T cells are important and essential for mediating the cellular host mechanisms required for control of enteric *Yersinia* spp.

CD₈ T cell responses have also been observed in murine and human yersiniosis. Moreover, the adoptive transfer of *Yersinia*-reactive CD₈ T cell clones can mediate immunity against a lethal challenge with *Y. enterocolitica*. However, the actual extent by which CD₈ T cells are involved in control of *Yersinia* infection remains to be further defined. Thus, in vivo depletion studies suggest a minor role of CD₈ T cells as compared with CD₄ T cells. However, in susceptible individuals such as BALB/c mice, IL-12-activated CD₈ T cells in concert with natural killer (NK) cells appear to be essential for pathogen control (Bohn et al., 1998a). In a *Yersinia* rat infection model, Lewis rats mount a *Yersinia*-specific RT-1-restricted CTL response (Falgarone et al., 1999). In this study, *Yersinia* invasin protein was required to mediate binding to blast target cells. In turn, YopE appeared to be translocated and presented via MHC class I molecules to CD₈ T cells. Both YopD and YopB were necessary for this process. The fact that Yop proteins are translocated into the cytosol of host cells explains a possible pathway of MHC class I antigen presentation for antigens of a bacterial pathogen that is extracellularly located. On the other hand, however, it is surprising that host cells that are

affected by several Yop proteins may still be capable of antigen processing, presentation and T cell stimulation. This is an issue that requires further molecular studies. Although acquired immune mechanisms usually succeed in control of *Yersinia* infections, enteric *Yersinia* spp. might interfere with this system and at least partially evade acquired immune responses. By translocation of YopH into the cytosol of T cells or B cells, *Yersinia* may impair calcium fluxes and their ability to be activated through their antigen receptors (Yao et al., 1999). T cells are inhibited in their ability to produce cytokines, and B cells are inhibited in their ability to upregulate surface expression of B7.2, an important costimulatory molecule. In consequence, such processes should significantly disturb cell-mediated immunity against the pathogen. As *Yersinia* may bind to integrins of B and T cells via invasin protein (Ennis et al., 1993), it is conceivable that lymphocytes, and thus the acquired immune response, is actually a target of the pathogenicity strategy of yersiniae *in vivo*. Interestingly, it was recently reported that *Yersinia* can translocate heterologous proteins such MAGE-A1 or *L. monocytogenes* p60 as fused to aa 1–130 of YopE into antigen-presenting (including dendritic) cells, which results in the presentation of antigenic peptides via MHC class I molecules (Chaux et al., 1999; Duffour et al., 1999; Ruessmann et al., 2000). These findings suggest that attenuated *Yersinia* strains might be suitable as a life vaccine carrier to induce MHC class I-restricted CTL responses against heterologous antigens.

In contrast to T cell responses, antibodies with protective abilities recognize the outer-membrane protein YadA of *Y. enterocolitica* (Vogel et al., 1993). Anti-LPS antibodies appear not to mediate significant protection. This might be explained by the fact that invasin or YadA, the two major outer membrane proteins of *Yersinia* might “cover” LPS structures. Consistently, studies in mice demonstrated that immunization with avirulent or virulent *Yersinia* mutant strains can confer immunity to challenge with highly pathogenic yersiniae and that antibodies against YadA are crucial in this process. Immunity conferred by YadA-specific antibodies appears to be serotype-specific, as antibodies against YadA from *Y. enterocolitica* serotype O:8 mediate protection against challenge with *Y. enterocolitica* O:8 pO:8 but not against challenge with *Y. enterocolitica* O:8 pO:9 (Vogel et al., 1993). Immunization of mice with an *S. typhimurium* strain expressing the outer-membrane protein *Yersinia* invasin induces anti-invasin antibodies in serum and intestinal secretion giving rise to inhibition of intestinal translocation, but failed to prevent *Yersinia* dissemination from the gut lymphoid tissue (Simonet et al., 1994). Together,

these data suggest that possibly different antigens are involved in the protective cellular and humoral immune responses.

Superantigens are microbial compounds that bind to conserved parts of MHC class II molecules and the V_B region of T cell receptors thereby triggering the activation of certain subtypes of T cells and antigen-presenting cells (Superantigen of *Y. pseudotuberculosis*). In *Y. pseudotuberculosis*, a mitogenic activity was found in the culture supernatants that exhibited superantigenic activity (Abe et al., 1993). The superantigen encoding gene, *ypmA*, was subsequently disrupted in *Yersinia* strains. By means of an experimental mouse infection model, it was observed that upon intravenous infection a *Y. pseudotuberculosis ypmA*-deficient mutant was not affected in its ability to colonize the spleen, liver or lungs (Carnoy et al., 2000). However, the survival rate of infected mice was increased, and thus the virulence of a *ypmA* mutant strain was significantly reduced suggesting that YpmA contributes to the virulence of *Y. pseudotuberculosis* (Carnoy et al., 2000). By contrast, *Yersinia ypmA* mutants did not show any specific phenotype upon intestinal infections (Carnoy et al., 2000). Unfortunately, it has not yet been investigated in this model whether the effect of YpmA on innate or acquired immunity is responsible for this effect, and the mechanism(s) by which YpmA induces a higher death rate remains to be elucidated. In contrast to this observation, *in vitro* studies provided evidence that YpmA may (indirectly) reduce active ion transport and permeability in human T84 epithelial cell monolayers (Donnelly et al., 1999). Moreover, colonic tissue from YpmA-treated mice displayed a diminished responsiveness to cAMP-mediated secretagogues and nerve stimulation (Donnelly et al., 1999). Together, these findings imply that YpmA may contribute to the enteric symptomatology upon *Y. pseudotuberculosis* infection. In conclusion, the significance of *Yersinia* superantigen for modulation of immunity is, therefore, not yet clear.

Mechanisms Involved in *Yersinia*-triggered Reactive Arthritis

Reactive arthritis is a “sterile” joint inflammation caused by infection with various microbial pathogens including enteric *Yersinia* spp. (Clinical manifestations of *Y. enterocolitica* infections). Although it is established that frequency of reactive arthritis is about 20-fold higher in patients with HLA B27 than in patients with other HLA alleles, the pathogenesis of reactive arthritis is still unknown. It is unclear how HLA B27 is linked to reactive arthritis. Several possible mechanisms including molecular mimicry or

whether HLA B27 is related to susceptibility for *Yersinia* infections have been discussed. Persistence of the pathogens is considered as an important factor in reactive arthritis and may depend on the genetic background of the host, the type of immune response mounted by the host, as well as on the arthritogenic potential of a given *Yersinia* strain. Thus, both a certain type of immunodeficiency that allows the persistence of the pathogen in host tissue, particularly at mucosal sites, as well as the generation of a strong immunopathological inflammatory response, are crucial in this process. In patients with reactive arthritis, immune complexes were demonstrated in the synovial fluid. Whether microbial antigens reach the joints as free antigens or as part of immune complexes is unknown. Previous studies failed to detect *Yersinia* DNA and/or viable yersiniae in the joints of these patients. A recent study, however, demonstrated the presence of *Y. enterocolitica* 16S rRNA in the synovial fluid of a patient (Gaston et al., 1999). These observations are in keeping with results from an experimental rat infection model of *Yersinia*-triggered reactive arthritis indicating that the pathogenicity, and thus, arthritogenicity of *Yersinia* spp., as well as complement, are important cofactors of reactive arthritis.

To the study the pathogenesis of this disease, a rat model of *Yersinia*-triggered reactive arthritis was established in 1987 and turned out to be clinically relevant and interesting (Hill and Yu, 1987). There are rat strains (e.g., Lewis rats) that develop reactive arthritis, while others (e.g., Fischer rats) do not (Gaede et al., 1992). As both Lewis and Fischer rats exhibit the identical MHC class I allele (RT.1), it appears unlikely that the MHC allele is the only gene linked to arthritis susceptibility. Interestingly, however, HLA B27 transgenic rats exhibit higher susceptibility for *Yersinia* infections than control rats. While certain highly pathogenic *Yersinia* wildtype strains induce reactive arthritis in rats, *Yersinia* mutants deficient in YadA, YopH or yersiniabactin production or uptake are attenuated and can no longer induce reactive arthritis in rats (Gaede et al., 1995c). Thus, the higher the virulence potential of a given *Yersinia* strain, the higher its potential for triggering reactive arthritis (Gaede et al., 1992; Gaede and Heesemann, 1995a). Moreover, de complementation of rats suppressed reactive arthritis triggered by *Yersinia* as determined clinically by an arthritis index, as well as by histomorphological investigations suggesting that complement and possibly immune complexes are involved in the pathogenesis of reactive arthritis (Gaede et al., 1995c). Interestingly, de complementation of rats did not change the bacterial numbers in infected organs, suggesting that the complement system does not sig-

nificantly contribute to the host defense against *Yersinia* (Gaede et al., 1995b). In the rat model, T cells appear to play a minor role in reactive arthritis, as treatment of rats with anti- α - β TcR antibodies modulated adjuvant arthritis, which is known to be T cell-mediated, but not *Yersinia*-triggered reactive arthritis (Gaede et al., 1995c). Preliminary data in this model indicate that during the very early phase of the infection, *Yersinia* bacteria can be detected and even grown in the joints of both rat strains, suggesting that during the early phase of *Yersinia* infection the bacteria actually reach the joints. In both rat strains, the bacteria are rapidly eliminated. After two weeks, however, Lewis rats develop reactive arthritis and no viable bacteria can be grown from the joints at this time point.

More recently, it was reported that U937 cell transfectants expressing various HLA B27 constructs or other HLA alleles were unaltered in their ability to internalize *Salmonella* and *Yersinia* (Virtala et al., 1997; Ortiz-Alvarez et al., 1998), but were impaired in their ability to eliminate *Salmonella enteritidis* (Virtala et al., 1997), suggesting that HLA B27 monocytes might contribute to persistence of microorganisms that trigger reactive arthritis. Unfortunately, the mechanisms that account for this impaired intracellular killing have not been elucidated. In contrast to this study, no effect of endogenous HLA B27 on the survival of *Yersinia* or *Salmonella* was found in primary fibroblast cells (Huppertz and Heesemann, 1996; Huppertz and Heesemann, 1997).

As HLA B27 is an MHC class I molecule, it is conceivable that MHC class I-restricted immune responses may play a role in reactive arthritis. Patients with *Yersinia*-triggered reactive arthritis were found to recognize several antigens of *Yersinia* on the humoral or cellular level: the 19-kDa β -urease subunit protein of *Y. enterocolitica* O:3 is recognized by IgG and IgA antibodies, as well as by synovial fluid mononuclear cells and correlates with a synovial cellular immune response (Appel et al., 1999). Although these studies did not elucidate the actual pathogenic role of a certain antigen, the antigens identified might be used in screening systems and thus might help to identify cases with *Yersinia*-triggered reactive arthritis. Others found a common intra-articular oligoclonal T cell expansion in patients with reactive arthritis, providing further evidence for a molecular mimicry phenomenon at the T cell level in which arthritogenic microbial peptides may be presented by HLA B27 molecules (Dulphy et al., 1999). On the other hand, recent work showed that enterobacterial infection may downregulate expression of MHC class I molecules, particularly in patients with HLA B27 (Kirveskari et al., 1999). Taken together, the

pathomechanism of reactive arthritis and the role of HLA B27 molecules in this process remains obscure. Moreover, the causative relationship between other autoimmune disease such as Graves' disease or Hashimoto's thyroiditis and *Yersinia* infections is still questionable and remains to be elucidated further (Arscott et al., 1992; Chatzipanagiotou et al., 2001).

Physiopathology (Francoise Guinet)

Introduction

While all *Y. pestis* and *Y. pseudotuberculosis* isolates are potentially pathogenic to humans, *Y. enterocolitica* is heterogeneous with respect to virulence. Pathogenic strains, which belong to biogroups 2–5 (generally of serotypes O:3, O:5,27 or O:9), possess an array of virulence factors, such as the pYV plasmid (The pYV virulence plasmid) and the chromosomally encoded Inv (Invasin), Ail and Myf (Other putative virulence factors) adhesins, which are not present in the innocuous strains of biotype 1A (Cornelis et al., 1987; Miller et al., 1989; Pierson and Falkow, 1990; Iriarte et al., 1993). Highly pathogenic *Y. enterocolitica* strains (biotype 1B, often associated with serotype O:8) harbor, in addition to the above-mentioned virulence factors, a pathogenicity island (High Pathogenicity Island) encoding proteins involved in iron uptake. These strains provoke lethal disseminated infections in mice (Carter, 1975) and cause more frequent extraintestinal infections in humans (Bottone, 1999).

The Enteropathogenic *Yersinia* Journey in Mammalian Hosts

COLONIZATION OF THE DIGESTIVE TRACT *Yersinia enterocolitica* and *Y. pseudotuberculosis* are enteric pathogens that normally enter the host through the oral route, usually by ingestion of contaminated food or water (Epidemiology of *Y. enterocolitica*). Ingested bacteria journey through the stomach and part of the gut lumen. A series of clinical case reports of *Y. enterocolitica* septicemia suggested that stomach acidity may play a role in controlling the severity of the infection (Foberg et al., 1986). In vitro experiments, however, demonstrated that enteropathogenic *Yersinia* can survive in an environment at pH lower than 2 for at least 90 min in the presence of urea (De Koning-Ward and Robins-Browne, 1995; Young et al., 1996; Riot et al., 1997). In these in vitro experiments, urea concentrations normally found in healthy human stomachs (1.4 M) were sufficient to confer acid

resistance to *Y. enterocolitica* but not to *Y. pseudotuberculosis*, which may explain the observed difference in ileum colonization at early time points after intragastric inoculation (De Koning-Ward and Robins-Browne, 1995; Riot et al., 1997).

In various animal models and in humans, *Yersinia* preferentially settle and proliferate in the terminal ileum and in the cecum (Carter, 1975; Pai et al., 1980; Robins-Browne et al., 1985b; Skurnik and Poikonen, 1986). One reason for this specificity is the accumulation at this locale of Peyer's patches, through which enteropathogenic *Yersinia* enter the digestive tract (see below).

Another factor accounting for this preferred localization might be variations in mucus secretion along the intestinal tract. It has been noted that maximal mucus secretion occurs in distal ileum and in proximal colon during experimental infections of rabbits with *Y. enterocolitica* (Pai et al., 1980). *Yersinia pseudotuberculosis* and pathogenic *Y. enterocolitica* strains are able to bind to intestinal mucus preparations (Mantle et al., 1989; Paerregaard et al., 1991), and *Y. enterocolitica* O:3 strains were shown to multiply at high rates within mucus but not in the intestinal content (Paerregaard et al., 1991). It is not clear, however, whether mucus acts as a host defense mechanism by entrapping the bacteria and expelling them into the gut lumen before they can contact the gut epithelium, or whether mucus serves as a niche where *Yersinia* concentrate before colonizing and penetrating the digestive epithelium. In favor of the second possibility, lack of *yadA* expression correlates with decreased binding to mucus (Mantle et al., 1989; Paerregaard et al., 1991) and with reduced Peyer's patch colonization beneath the epithelium (Marra and Isberg, 1997). On the other hand, penetration of wild-type *Y. enterocolitica* through rabbit ileal mucus reduces subsequent attachment to brush border membranes, to levels comparable to those of an isogenic plasmidless derivative (Paerregaard et al., 1991). Perhaps, the best evidence so far for mucus binding being advantageous to the bacteria is that, at least for one *Y. enterocolitica* strain, the affinity to mucins from various species (human, rabbit and rat) correlates with the virulence potentials toward those animal species (Mantle et al., 1989).

It is conceivable that sequential deployment of adhesin expression during *Yersinia*'s journey directs the bacteria to specific settling and progression sites within the host (Isberg, 1990a; Bottone, 1999). For instance, expression of *yadA* was found to occur as early as 1 h after oral inoculation of *Y. enterocolitica* O:3 in rats, when the microorganism is present in the terminal ileum (Skurnik and Poikonen, 1986). Under in

vitro conditions, the temperature of maximal expression of the *ail* and *yadA* genes is the host temperature, i.e., 37°C (Kapperud et al., 1985; Bottone, 1999), but the *inv* gene (Invasin) is maximally expressed at temperatures below 30°C, which is paradoxical given invasins' primary importance in Peyer's patch colonization (see below). However, in a low pH environment, as can be encountered in the gastrointestinal tract, *inv* expression at 37°C is increased to levels similar to that of bacteria grown at 23°C (Pepe et al., 1994).

TRANSLOCATION THROUGH THE GUT EPITHELIUM Confirming earlier observations (Carter, 1975; Falcao et al., 1984), studies by Hanski et al. (1989) established that Peyer's patch (PP) is the main portal of entry for pathogenic *Y. enterocolitica* into the gut tissue. After oral infection, mouse PPs were 1000 times more heavily colonized than the surrounding mucosa, so that between 19 and 63 h postinfection, the number of bacteria in a single PP was equivalent to that in the rest of the ileal mucosa. Peyer's patches are specialized areas of the digestive tract, consisting of lymphoid follicles overlaid by the follicle-associated epithelium (FAE; Immunology). At the edge of FAE are cells devoid of a regular brush border, the so-called "M cells," which sample antigens from the intestinal lumen and translocate them to lymphocytes and macrophages residing in the basolateral pocket of these cells. Like other enteroinvasive pathogens, *Y. pseudotuberculosis* (Marra and Isberg, 1997; Clark et al., 1998) and pathogenic *Y. enterocolitica* species (Hanski et al., 1989; Grutzkau et al., 1990; Autenrieth and Firsching, 1996a) have been shown to utilize M cells to traverse the epithelial barrier. The *Yersinia* adhesin Inv binds to β 1-integrins apically expressed at the surface of M cells, thereby promoting internalization of the bacteria and its delivery to the basolateral side of the cell (Clark et al., 1998; Schulte et al., 2000). The Inv/ β 1-integrin pathway is not the only way for enteropathogenic yersiniae to reach PPs in vivo, as an *inv yadA Y. pseudotuberculosis* double mutant was found to colonize PPs at early time points (90 min) even more efficiently than the wildtype (Marra and Isberg, 1997). However, the double mutation does not impart increased mouse virulence to *Y. pseudotuberculosis* (Han and Miller, 1997), contrary to an earlier report (Rosqvist et al., 1988). Also, *inv* mutants that express YadA appear to be trapped in the mucus layer lining the gut (Marra and Isberg, 1997), and they poorly colonize PPs as assessed by bacterial counts at 90 min (Marra and Isberg, 1997), 6 h and 18 h (Pepe and Miller, 1993). Therefore, the β 1-integrin/Inv interaction appears to be critical for liberating the bacteria from the mucus layer

to which they attach through their YadA fibrillae. The nature of the alternative ligand receptor pair permitting translocation through the digestive epithelium in the absence of Inv and YadA is not known, although it is likely that passage through M cells, here again, accounts for the specific targeting to PPs. Nonpathogenic *Y. enterocolitica*, which are devoid of the Inv, Ail and YadA adhesins, are rapidly eliminated from the host and display reduced or no gut wall invasive potential (Une, 1977a; Robins-Browne et al., 1985b).

Yersiniae are internalized almost exclusively by M cells, both in ligated-loop experiments (Autenrieth and Firsching, 1996a; Marra and Isberg, 1997) and in vitro (Schulte et al., 2000), which is in agreement with the fact that M cells, but not polarized enterocytes, express β 1-integrins on their apical side (Beaulieu, 1992; Clark et al., 1998; Schulte et al., 2000). However, it was recently shown in two epithelial cell lines that β 1-integrins exposed on the apical side of the tight junctions allowed for Inv-mediated binding of luminal *Y. pseudotuberculosis* and breaching of the epithelium through the cytotoxic effect of YopE (Tafazoli et al., 2000). The relevance of this finding in vivo remains to be elucidated.

ESTABLISHMENT WITHIN PPs After crossing M cells, pathogenic yersiniae proliferate locally within the PPs where they have been described, in various animal models, as extracellular colonies surrounded by phagocytes that display little or no phagocytic activity (Une, 1977b; Robins-Browne et al., 1985b; Lian et al., 1987; Hanski et al., 1989; Simonet et al., 1990; Grutzkau et al., 1993; Autenrieth and Firsching, 1996a). Phagocytosis inhibition is due to the activation of the pYV virulence plasmid harbored by pathogenic *Yersinia* strains (The pYV virulence plasmid). Strains cured of the pYV plasmid appear to be able to cross the digestive epithelium, but they are then rapidly eliminated from the host (Robins-Browne et al., 1985b; Skurnik and Poikonen, 1986; Lian et al., 1987; Grutzkau et al., 1993). Intraphagocytic pYV⁺ yersiniae have been reported, but their viability has usually not been assessed (Skurnik and Poikonen, 1986; Lian et al., 1987; Pepe et al., 1995; Nikolova et al., 1997). One exception is the report of some actively dividing bacteria within phagocytes of piglets that had been infected per os, 1–6 days earlier, with a 4/O:3 *Y. enterocolitica* strain (Robins-Browne et al., 1985b).

While YadA has an ambiguous effect at the initial step of translocation across the epithelium (Paerregaard et al., 1991; Marra and Isberg, 1997), it is clearly necessary for *Y. enterocolitica* maintenance in mouse PPs (Pepe et al., 1995). This role is likely to be of critical importance for pathogenicity, as *Y. enterocolitica yadA* mutants

are totally avirulent (Pepe et al., 1995). For unclear reasons, YadA does not play the same role in *Y. pseudotuberculosis*, since *yadA* inactivation does not reduce virulence in this species (Bölin and Wolf-Watz, 1984; Han and Miller, 1997) nor ileum colonization (Kapperud et al., 1987b).

It is possible that binding of pathogenic yersiniae to extracellular matrix components is part of the gut wall colonization process. Collagen and laminin inhibit binding of various *Y. enterocolitica* strains to human intestine wall (Skurnik et al., 1994). *Yersinia enterocolitica* and *Y. pseudotuberculosis* YadA expression confers specific binding of *E. coli* constructs to purified type I, II, and IV collagen (Emody et al., 1989) and to fibronectin-coated coverslips (Tertti et al., 1992). The collagen binding properties are different for *Y. enterocolitica* and *Y. pseudotuberculosis* because the pYV plasmid is necessary for binding to type I, II and IV collagen in the former species, and only for binding to type I and type II collagen in the latter (Emody et al., 1989).

The extracellular PP environment is rich in serum proteins, including complement, which diffuse from blood vessels. Pathogenic yersiniae grown at 37°C manifest a high degree of resistance to the bactericidal action of serum from various species, including humans (Une and Brubaker, 1984). Complement depletion in mice by injection of cobra venom factor confirmed that, in mice, complement is not essential for the elimination of *Y. enterocolitica* (Hanski et al., 1991). Plasmid-encoded YadA and chromosome-encoded Ail have been implied in resistance to serum (Balligand et al., 1985; Tertti et al., 1987; Bliska and Falkow, 1992; Pierson and Falkow, 1993; Wachtel and Miller, 1995), although other studies failed to find a role of the *Y. enterocolitica* virulence plasmid in resistance to serum (Hanski et al., 1991) or in *Y. pseudotuberculosis* (Perry and Brubaker, 1983). Hence, resistance to serum is probably essential for yersiniae to settle within PPs. It might also be important for further spreading out through lymphatic or blood vessels, although intracellular spreading cannot be ruled out (see below).

FROM PPs TO OTHER ORGANS In the clinical setting, systemic infections by enteropathogenic yersiniae occur mostly in patients with underlying diseases and immunosuppressed conditions. Particularly prone are those patients with iron overload or treated with the iron-chelating agent desferrioxamine (Carniel, 1999; Other virulence factors, 3. Iron uptake systems). In previously healthy patients, the disease is usually limited to the gut wall or regional lymph nodes, although enteropathogenic yersiniae harboring the yersiniabactin-encoding high pathogenicity island

(i.e., *Y. pseudotuberculosis* I and III and *Y. enterocolitica* 1B) manifest a higher capability to spread in vivo and cause systemic infections (Bottone, 1999; Carniel, 1999; High Pathogenicity Island).

The likely route of emigration to mesenteric lymph nodes is via lymphatic vessels, whose function is indeed to drain tissue antigens toward lymph nodes. In rabbits, *Y. enterocolitica* organisms were seen in dilated lymphatic vessels of the lamina propria within 4 h after per os inoculation (Lian et al., 1987). After massive per os infection of mice with a highly virulent O:8 strain, bacteria were also occasionally seen in blood vessels at early times (3 h) after infection, thus probably accounting for the observed dissemination to other organs such as liver and spleen (Autenrieth and Firsching, 1996a). Notably, studies by Pepe and Miller uncovered an alternative route, bypassing PPs, for dissemination of *Y. enterocolitica* *inv* mutants from mouse gut lumen to liver and spleen (Pepe and Miller, 1993). *Yersinia enterocolitica* and *Y. pseudotuberculosis* *inv* mutants are as virulent in mice as their wild-type counterparts (Pepe and Miller, 1993; Han and Miller, 1997). In the *Salmonella* genus, it was recently shown that mutants deficient in invasion genes can bypass PPs and be directly transported from the gastrointestinal tract to the bloodstream inside CD₁₈-expressing phagocytes (Vazquez-Torres et al., 1999). Although enteropathogenic yersiniae, unlike *Salmonella*, are mostly extracellular in PPs (Hanski et al., 1989), liver and spleen (Simonet et al., 1990), there are some lines of evidence suggesting that intracellular spreading might be utilized by yersiniae as well. Actively replicating pathogenic *Y. enterocolitica* were occasionally seen within phagocytes of animal gut walls after oral infections (Robins-Browne et al., 1985b). A recent report shows that *Y. pseudotuberculosis* can survive and replicate in macrophages in vitro by blocking phagosome acidification (Tsukano et al., 1999), and human neutrophils have the ability to translocate viable *Y. enterocolitica* through endothelial monolayers (Russmann et al., 1996). Additionally, reduced dissemination to the spleen has been observed in mice pretreated with antibodies specific for the CD_{11b}/CD₁₈ heterodimer, which is expressed on the phagocyte surface (Autenrieth et al., 1996b). Noting that the $\alpha 4\beta 1$ -integrin, which is involved in the homing of T lymphocytes to PPs, is the invasin receptor found on human T cell lines, Isberg also suggested that invasin, by binding to circulating lymphocytes, could promote bacterial spread within the host (Isberg, 1990a; Invasin).

Histopathology

ANIMAL MODELS Mice challenged orally with high bacterial loads (e.g., 5×10^8 bacteria) have

been widely used for histopathological studies of *Y. enterocolitica* infections. In this model, the highly pathogenic 1B/O:8 bioserotype causes disseminated infections (Carter, 1975; Falcao et al., 1984), while low-pathogenic strains (biotypes 2–5) can establish long-term intestinal infections involving the PPs (Falcao et al., 1984; Ruiz-Bravo et al., 1999). In mice inoculated per os with a O:8 *Y. enterocolitica* strain, alterations of the gut wall include extensive bacterial proliferation in the PP's lymphoid follicle, and a major neutrophil reaction that within a few days results in PP destruction and surface ulcerations (Hanski et al., 1989; Grutzkau et al., 1993; Autenrieth and Firsching, 1996a). Various other laboratory animals have been used, including rabbits, rats, pigs and gnotobiotic piglets (Une, 1977a; Une, 1977b; Pai et al., 1980; Robins-Browne et al., 1985b; Skurnik and Poikonen, 1986; Nikolova et al., 1997). *Yersinia enterocolitica* in rabbits exhibit a higher tendency than in mice to elicit granulomatous responses (Une, 1977a; Robins-Browne et al., 1985b).

IN HUMANS

Yersinia enterocolitica Enterocolitis is the most common clinical presentation of *Y. enterocolitica* infection (West, 1997; Clinical manifestations of *Y. enterocolitica* infections). The corresponding histopathological images are those of a diffuse inflammatory reaction involving a prominent neutrophil influx in the lamina propria, without visible bacteria. Foci of superficial mucosal ulcerations can be present. Pathogenic *Y. enterocolitica* strains produce a heat-stable enterotoxin (YST, later named "YSTa") that is toxic to infant mice and induces diarrhea in young rabbits (Delor and Cornelis, 1992; Other virulence factors, 1. Heat stable enterotoxins). The *yst* gene is present in pathogenic strains and absent among nonpathogenic strains (Huang et al., 1997). Transcription of *yst* is induced in experimental conditions (temperature, pH, and osmolarity) similar to those of the ileum lumen (Mikulskis et al., 1994). YSTa toxin is thus likely to be important for pathogenicity, in spite of some discrepancies between YSTa expression and occurrence of symptoms in humans and laboratory animals (Robins-Browne et al., 1985b; Cover and Aber, 1989; Morris et al., 1991). Recently, two additional enterotoxins were discovered, but their role in pathogenicity is not established (Nair and Takeda, 1998).

Infection by *Y. enterocolitica* sometimes results in terminal ileitis, which histologically displays features of an invasive infection accompanied by a nonspecific acute inflammatory reaction, fitting pictures observed in animal models. Histopathological alterations in the ter-

минаl ileum and proximal colon are mostly restricted to PPs. In the PP lymphoid follicles, colonies of bacteria are overlaid by microabscesses. The necrotizing processes eventually disorganize the lymphoid follicle and erupt at the surface, creating well-delimited ulcerations over the PP areas. Histiocytes and lymphocytes can be seen beneath the microabscesses and the bacteria. Mesenteric nodes are enlarged and exhibit a lymphocytic reaction with necrotic foci that often contain colonies of *Y. enterocolitica*.

Yersinia pseudotuberculosis Contrary to *Y. enterocolitica*, acute enterocolitis and terminal ileitis are infrequent during *Y. pseudotuberculosis* infections, which typically result in mesenteric adenitis without visible bacteria (Gaulier and Poulton, 1983; West, 1997). As a consequence, *Y. pseudotuberculosis* is more rarely isolated from stools than *Y. enterocolitica*. Eight out of 13 (61.5%) *Y. pseudotuberculosis* clinical isolates characterized at the French National Reference Laboratory for *Yersinia* in 2000 were isolated from blood or organs, as opposed to 18 out of 176 (10.2%) pathogenic *Y. enterocolitica* clinical strains. Another difference between the two genera is that clinical and histopathological features suggest an acute disease in the case of *Y. enterocolitica* infections, while *Y. pseudotuberculosis* infections seem to evolve on a more subacute basis (Mollaret and Destombes, 1960c; West, 1997). Characteristically associated with *Y. pseudotuberculosis* infections is a strong macrophage reaction in the paracortical area of mesenteric lymph nodes, sometimes in the form of epithelioid granulomas of the tuberculoid type. The species name of this bacterium was coined from these tuberculosis-like reactions. Microabscesses seem to appear secondarily in the center of the granulomas. A lymphoid reaction inside and outside the germinal centers can be present.

Antibiotic Susceptibility, Treatment and Prevention (Jeannette Pham)

Antibiotic Susceptibility

YERSINIA PSEUDOTUBERCULOSIS *Yersinia pseudotuberculosis* clinical isolates are susceptible to most commonly used antibiotics such as ampicillin, cefotaxime, doxycycline, chloramphenicol, cotrimoxazole, nitrofurantoin and the fluoroquinolones. β -Lactamase has not been detected in isolates of this species (Jupeau et al., 1982; Van Noyen et al., 1995). By contrast, more than 50% of strains are resistant to the polymyxins in general and to colistin (polymyxin E; Jupeau et al., 1982; Van Noyen et al., 1995). Resistance to tetracycline has also been reported in some strains

of *Y. pseudotuberculosis* isolated from animals and birds (Reece and Coloe, 1985; Kanazawa et al., 1987).

YERSINIA ENTEROCOLITICA With the exception of β -lactam antibiotics, clinical isolates of *Y. enterocolitica* show in vitro susceptibility to antibiotics (such as gentamicin, chloramphenicol, cotrimoxazole and the fluoroquinolones) commonly used in Gram-negative infections, although a low number of isolates are resistant to tetracycline (Raevuori et al., 1978; Jugeau et al., 1982; Stock and Wiedemann, 1999).

Two types of chromosomal β -lactamase were described in *Y. enterocolitica*, the noninducible broad spectrum β -lactamase enzyme A with an isoelectric point (pH) of 8.7 and the inducible cephalosporinase enzyme B with pH's of 5.3 and 5.7 (Cornelis et al., 1973; Cornelis and Abraham, 1975). Strains of serotypes O:1, O:2, O:3 and O:9 produced two types of β -lactamase, enzyme A and enzyme B, while strains of serotype O:5,27 produced only enzyme B (Matthew et al., 1977); clusters of susceptibility to β -lactam antibiotics corresponding to the major serotypes have been observed (Hornstein et al., 1985). Environmental strains of *Y. enterocolitica* belonging to biotype 1A produce the broad spectrum enzyme A and an enzyme "B-like," a range of cephalosporinases similar to enzyme B, but with a different pH ranging from 6.2 to 7.3 (Pham et al., 2000). It has been demonstrated that although the genes encoded for both types of β -lactamase A and B are present in all *Y. enterocolitica*, they are not always active (De la Prieta et al., 1995).

In vitro, *Y. enterocolitica* are uniformly susceptible to cefotaxime, ceftriaxone, ceftazidime, aztreonam, cefpirome, imipenem and meropenem (Preston et al., 1995; Stock and Wiedemann, 1999; Pham et al., 2000). The susceptibility pattern of ticarcillin, cefoxitin and amoxicillin/clavulanate is specific to each biotype or subtype and depends on the extent of elaboration or the absence of one of the two β -lactamases, enzyme A and enzyme B (Pham et al., 2000). Owing to the lack of expression of enzyme A, biotype 2 (serotype O:5,27) strains are susceptible to ticarcillin (Pham et al., 1999). On the other hand, a number of *Y. enterocolitica* 4/O:3 isolated in Canada and all 4/O:3 strains isolated in Australia and New Zealand are highly susceptible to amoxicillin/clavulanate due to the absence of the cephalosporinase enzyme B (Pham et al., 1995). The borderline susceptibility to ampicillin often reported with strains of *Y. enterocolitica* biotype 1B, serotype O:8 originally isolated in North America is due to the presence of an enzyme "A-like" similar to enzyme A. This type β -lactamase has a slight shift in pH and is not as efficient in hydrolyzing ampicillin as

enzyme A expressed by strains of bioserotypes 2/O:9, 3/O:1,2a,3 and 4/O:3 (Pham et al., 2000).

Treatment

YERSINIA PSEUDOTUBERCULOSIS Although, in vitro, *Y. pseudotuberculosis* are susceptible to all antibiotics commonly used, cefotaxime and especially ciprofloxacin are more efficient than cotrimoxazole and ampicillin in clinical situations (Jugeau et al., 1982; Nesbitt et al., 1994).

YERSINIA ENTEROCOLITICA Most patients with gastroenteritis recover without antibiotic treatment and antibiotic therapy. Although treatment shortens the intestinal carriage, it does not change significantly the duration of symptoms. First generation cephalosporins and amoxicillin/clavulanate are not effective when used alone in *Y. enterocolitica* septicemia (Gayraud et al., 1993), while intravenous cotrimoxazole, cefotaxime, ceftriaxone, alone or in combination with gentamicin, have been used successfully (Gayraud et al., 1993; Zhang et al., 1996a). Ciprofloxacin has been used with great success in *Y. enterocolitica* septic arthritis and osteomyelitis (Crowe et al., 1996).

Vaccines

No vaccines are available for *Y. pseudotuberculosis* and *Y. enterocolitica* infections.

Concluding Remarks (Elisabeth Carniel)

Since the emergence of *Y. pseudotuberculosis* and *Y. enterocolitica* as important human enteropathogens in the late 1960s, major advances have been made in the knowledge of the biology of these two species. However, what we currently know represents only the tip of the iceberg. One of the most promising tools for gaining a much deeper understanding of these bacteria is comparative genomics. The genomes of two strains of *Y. pestis*: (http://www.sanger.ac.uk/Projects/Y_pestis/{CO92}) (Sanger center) and (<http://www.genome.wisc.edu/html/pestis.html{KIM5}>) (University of Wisconsin) have been sequenced. The sequencing of the genomes of *Y. pseudotuberculosis* is close to being finished (Lawrence Livermore National Laboratory) (<http://www.greenengenes.llnl.gov/bbrp/html/microbe.html{IP32953}>) and that of *Y. enterocolitica* (http://www.sanger.ac.uk/Projects/Y_enterocolitica/{Ye8081}) is in progress (Sanger center). The comparison of these genomes, in association with functional studies, will most likely bring a tremendous amount of new information about the

biology of these species and the factors that define each species' specificities. The comparison with other Enterobacteriaceae genomes should also be extremely useful in understanding the evolution of the different members of this family.

LINKS LPS

Link 1: *Y. pseudotuberculosis* serotypes

The current *Y. pseudotuberculosis* antigenic scheme lists 15 O-serotypes (Tsubokura and Aleksic, 1995) of which the five first contain O-subtypes. The division into these types is based on ca. 30 O-factors (Table 29).

Differences in the first seven serotypes are in part determined by the presence of different DDHs (3,6-dideoxyhexoses) in the O-antigen. Many *Salmonella* and *E. coli* serotypes also contain DDHs in their LPS, which causes antigenic crossreactivity between them and *Y. pseudotuberculosis* serotypes (Tsubokura et al., 1984; Tsubokura et al., 1993). Epidemiologically, there are some differences in prevalence of the serotypes in human isolates. In Europe, the isolates belong most often to serotypes O:1–O:3 (Aleksic et al., 1995), while in Japan, they belong to serotypes O:4b, O:3, O:5a, and O:5b (Tsubokura et al., 1989). Apparently, the more recently recognized serotypes represent environmental *Y. pseudotuberculosis*, since they do not carry the virulence plasmid (Tsubokura and Aleksic, 1995; Nagano et al., 1997b).

Link 2: Serotypes of *Y. enterocolitica* and related species

In *Y. enterocolitica* and related species, there are over 70 serotypes, which are mainly determined by the variability of the O-antigen (Wauters et al., 1991). Human and animal pathogenic strains of *Y. enterocolitica* that carry the virulence plasmid pYV (70–75 kb virulence plasmid of *Yersinia*) belong to certain serotypes; in Scandinavia and Europe, Canada, Japan, and South Africa, to O:3 and O:9, and in the United States, to O:8. Less frequently encountered pathogenic serotypes are O:4,32, O:5,27, O:13a,18, and O:21 (Table 30).

Yersinia enterocolitica strains of certain serotypes do not carry the pYV (Table 30) and these are collectively referred to as nonpathogenic or environmental serotypes. However, strains belonging to these serotypes are often isolated from stool samples of healthy humans. The virulence of different pathogenic serotypes varies, i.e., serotype O:8 strains are more virulent than those of serotypes O:3 or O:9. This is most evident as mouse lethality. The O:8 strains kill mice,

while the others do not unless iron is made available to the bacteria by pretreatment of mice with desferrioxamine or iron (Robins-Browne and Prpic, 1985a). On the other hand, O:3 strains frequently cause reactive arthritis in humans, while O:8 do so extremely rarely. It is not clear if O-antigen has any role in determining the differences in the virulence between the serotypes or whether this is due to other factors.

Serotype O:9 O-antigen crossreacts with *Brucella abortus* O-antigen causing diagnostic problems in serological confirmation of *Brucella abortus* infections (Ahvonen et al., 1969; Kittelberger et al., 1995a; Kittelberger et al., 1995b).

Link 3: LPS biosynthesis

Polysaccharide biosynthesis precursors.

In Nature, biosynthesis of any kind of oligo- or polysaccharides involves NDP (nucleoside diphosphate)-activated sugars that function as sugar donors and corresponding glycosyltransferases that catalyze the transfer of the sugar moiety from NDP to the acceptor structure. Each sugar, acceptor structure, and specific glycosidic linkage between the sugar and acceptor structure needs its own specific glycosyltransferase.

LPS biosynthesis starts by the activation of sugar-1-P (phosphate), such as Glc (glucose)-1-P or Fru (fructose)-1-P by reaction with NTP (nucleoside triphosphate) to form NDP-activated sugars. The activation reactions take place in the cytoplasm, catalyzed by soluble enzymes. Different NDP-sugars are then synthesized in several enzymatic steps involving epimerases, reductases, hydratases, etc. Different NTP are used to activate different sugars, e.g., GTP for Man (D-mannose) and Rha (D-rhamnose), CTP for Abe (D-abequose) and Par (D-paratose) UTP for Gal (D-galactose) and Glc (D-glucose), and dTTP for L-Rha; the reason for the choice is unclear. A few NDP-sugars needed for LPS biosynthesis are present in bacteria as intermediates of general metabolism; however, most of them have to be synthesized specifically for this purpose.

Lipid A – core biosynthesis.

Lipid A is assembled on the cytoplasmic face of the inner membrane (IM). In several enzymatic steps UDP-GlcNAc and fatty acids (supplied by acyl carrier protein) are converted into lipid A, which is a polar lipid with a backbone of GlcN-b-(1→6)-GlcN substituted with 4–7 N- and O-linked saturated fatty acid residues and 1–2 phosphate groups. The core oligosaccharide typically contains 10–15 sugar residues and is built on lipid A sequentially by specific glycosyltransferases that transfer the sugars from NDP-activated sugar precursors. The completed lipid

A-core molecules are translocated to the periplasmic face of the inner membrane (IM) where the O-antigen ligase, WaaL, ligates the O-specific polysaccharide (see below) to some of them. From the IM, the LPS molecules are finally translocated to the outer membrane (OM).

O-antigen biosynthesis.

The O-polysaccharide can be either homo- or heteropolymer (Fig. 38), i.e., a polymer of a single sugar or a polymer of repeats of different sugars (O-units), respectively, and their biosynthesis differs in some respects. Both types of O-polysaccharides have been found in the genus *Yersinia* (Link 4: *Y. enterocolitica* serotype O:3 LPS, Link 7: *Y. enterocolitica* serotype O:8 LPS).

Most steps in the O-antigen biosynthesis take place in the cytoplasmic face of the IM.

In the “heteropolymeric pathway,” each identical repeat unit is first assembled on a carrier lipid, Und-P (undecaprenol phosphate, a 55-carbon isoprenoid carrier lipid). Remarkably, the initiation reaction, transfer of the first sugar-1-P to Und-P, is in many strains accomplished by WecA, a GlcNAc-1-P transferase, the gene of which is located in the ECA (enterobacterial common antigen) gene cluster. In a few strains a dedicated transferase, such as a Gal-1-P transferase, is used for initiation. The O-unit assembly is then continued by dedicated glycosyltransferases that use NDP-activated sugar precursors. ‘Flippase’ protein, Wzx (Liu et al., 1996), translocates the completed Und-PP-O-unit to the periplasmic side of the IM. There, O-antigen polymerase, Wzy, polymerizes the O-units into long chains still carried by Und-P. The chain length determinant protein Wzz regulates the chain length. The polymerized chains are transferred from Und-P to the preformed lipid A-core structure by O-antigen ligase, WaaL.

In the “homopolymeric pathway,” the O-antigen polymer is synthesized on Und-P and completely elongated to full length in the cytoplasmic side of the IM by sequential transfer of sugar residues to the nonreducing end of the growing polysaccharide chain. The completed O-antigen is translocated to the periplasmic side by an ATP-driven transporter system, composed of Wzt and Wzm, that belongs to the ABC (ATP-binding cassette) transporter family (Whitfield, 1995). The O-antigen ligase, WaaL, transfers and ligates also the homopolymeric O-antigen onto lipid A-core.

GENETICS LPS biosynthesis requires enzymes that are specific for each LPS component and linkage, therefore the number of LPS genes is at least 50 and the genes are chromosomally located in most Gram-negative bacteria. The genes involved in lipid A biosynthesis are usually scattered around the genome, whereas those

involved in core biosynthesis form a distinct gene cluster as do the genes involved in O-antigen biosynthesis. In a few bacteria, LPS genes are found on plasmids or on temperate bacteriophage genomes.

Link 4: *Y. enterocolitica* serotype O:3 LPS

The lipid A structure is not known. The inner and outer core structures as well as that of the O-antigen are known (Radziejewska-Lebrecht et al., 1994; Radziejewska-Lebrecht et al., 1998; Table 31). Silver stained LPS from wildtype and outer core mutant strains of *Y. enterocolitica* O:3 are shown in Fig. 41, along with a schematic structure of the wild-type LPS.

The molecular genetic studies indicate that the outer core hexasaccharide of O:3 is an ancestral heteropolymeric O-unit (Skurnik et al., 1995). Furthermore, the structure of the *Y. enterocolitica* O:3 LPS is unique since the present O-antigen, which is a homopolymer of 6d-Alt (6-deoxy-L-altropyranose; Hoffman et al., 1980), is not attached to the outermost tip of the outer core but instead to the inner core (Skurnik et al., 1995). Similarly, in the enterobacterial common antigen lipopolysaccharide (ECA-LPS), the ECA moiety is ligated to the inner core (Radziejewska-Lebrecht et al., 1998).

Link 5: *Y. enterocolitica* serotype O:3 outer core

Biosynthesis of the outer core.

The biosynthesis of the outer core hexasaccharide (Fig. 42) needs 1) enzymes for the biosynthesis of NDP-sugar precursors, 2) six

Fig. 41. *Y. enterocolitica* O:3 lipopolysaccharide (LPS). At left, silver stained deoxycholate polyacrylamide gel electrophoresis (DOC-PAGE) analysis of LPS: Left lane, LPS of wild-type, and right lane, LPS of mutant bacteria missing the outer core. At right, schematic structure of LPS.

O:21, O:25,26,44, O:41(27)43, O:41,43, and O:50 strains, and in *Y. intermedia* O:52,54 strain (Skurnik et al., 1995). Phage resistant variants of some of these strains were analyzed by deoxycholate polyacrylamide gel electrophoresis (DOC-PAGE) and all had lost the outer core (Müller-Loennies et al., 1999; E. Ervelä and M. Skurnik, unpublished observation).

Link 6: *Y. enterocolitica* serotype O:3 O-antigen

The *Y. enterocolitica* O:3 O-antigen (Fig. 37) is a homopolymer of 6d-Alt (6-deoxy-L-altropyranose; Table 31) which is linked to the inner core of LPS (Hoffman et al., 1980; Skurnik et al., 1995). Genetic evidence indicates that the reducing end sugar is GlcNAc (see below). An O-antigen gene cluster, able to direct the synthesis of the homopolymeric O-antigen, must contain genes for 1) the biosynthesis of the NDP-activated sugar precursor, 2) at least two glycosyltransferases (one to initiate the O-antigen synthesis and the other to extend the homopolymer), and 3) a transporter system. Also, 6d-Alt is a carbon-3 epimer of L-Rha, and their biosynthetic pathways start similarly having dTDP-4-keto-6-deoxy-D-Glc as an intermediate. Biosynthesis of dTDP-L-Rha takes place in four steps, and the same is expected also for 6d-Alt. However, details of the dTDP-6d-Alt biosynthesis are not yet known and will need to be elucidated.

The O:3 O-antigen gene cluster (Table 32) contains 8 genes.

Upstream of the cluster are two ORFs of unknown function; there are no similar sequences in GenBank. The O-antigen cluster is organized into two operons and both operons are transcribed under tandem promoters; one is 1.2 kb upstream of *wbbS* and the other between *wbbU* and *wzm* (Zhang et al., 1993). The O-antigen expression is under temperature regulation; optimal expression takes place below 30°C. The first operon contains three genes *wbbS*, *wbbT* and *wbbU* and the second, five: *wzm*, *wzt*, *wbbV*, *wbbW* and *wbbX*, and all genes are essential for O-antigen synthesis (Al Hendy et al., 1991; Al Hendy et al., 1992; Zhang et al., 1993). There is a noncoding 1.5-kb region upstream of *wbbS* that contains relics of the *rmlB* gene and the regulatory JUMPstart sequence.

Biosynthesis of the O-antigen.

WbbS, *WbbV* and *WbbW* are significantly similar to *RmlC*, *RmlD*, and *RmlA*, respectively, the enzymes involved in the dTDP-L-Rha biosynthesis, indicating that they function in dTDP-6d-Alt biosynthesis. The initiation of the O-antigen biosynthesis is *WecA* (GlcNAc-transferase) dependent (Zhang et al., 1996b). Thus the O-antigen biosynthesis utilizes an initiation step

where a single GlcNAc residue is transferred to Und-P. After this, a specific 6d-Alt-transferase transfers the first 6d-Alt residue to GlcNAc-Und-PP, upon which the homopolymer is then sequentially built up by a second 6d-Alt-transferase that uses (6d-Alt)_n-GlcNAc-Und-PP as an acceptor. Both *WbbT* and *WbbU* share conserved local motifs with a number of glycosyltransferases (Morona et al., 1995; Skurnik et al., 1995), and fulfill the need for two glycosyltransferases.

O-antigen transport.

Wzm and *Wzt* make up an ATP-driven polysaccharide transporter system that transports the Und-PP-bound O-antigen to the periplasmic space (Zhang et al., 1993; Whitfield, 1995). Transposon insertions into the *wzm* and *wzt* genes result in accumulation of cytoplasmic O-antigen (Zhang et al., 1993). *Yersinia enterocolitica* O:3 was the first organism where an ATP-driven polysaccharide transport system was recognized in an O-antigen gene cluster.

Serotype O:3 related serotypes.

6d-Alt is the major component of *Y. enterocolitica* O:1,2a,3 and O:2a,2b,3 O-antigens (Table 31). The genetic organization of the O-antigen gene clusters of these organisms is not known. The O:3 O-antigen cluster DNA hybridizes strongly with DNA from these organisms, indicating the presence of similar clusters (Al Hendy et al., 1991).

Link 7: *Y. enterocolitica* serotype O:8 LPS

Structure of *Y. enterocolitica* O:8 LPS

Silver stained deoxycholate polyacrylamide gel electrophoresis (DOC-PAGE) and a schematic structure of the LPS of *Y. enterocolitica* O:8 is shown on Fig. 43. Details of the chemical structure are given in Table 31. The inner core structure is very similar to that of O:3 and O:9. The O-unit is a branched pentasaccharide. Interestingly, the O-antigens of serotypes O:7,8 and O:19,8 are almost identical to that of O:8 (Table 31).

Link 8: *Y. enterocolitica* serotype O:8 O-antigen

Biosynthesis of O-antigen.

The O:8 O-unit is a branched pentasaccharide (Fig. 44). The gene cluster for the biosynthesis of the O-antigen should contain 1) biosynthetic genes for each individual NDP-sugar (except for UDP-Gal, the biosynthesis of which belongs to general metabolism), 2) genes for five glycosyltransferases, one for each residue, 3) the *wzx* gene for flippase needed in heteropolymeric O-antigen transport, 4) the *wzy* gene for O-antigen

polymerase, and 5) the *wzz* gene for the chain length determinant.

The *Y. enterocolitica* O:8 O-antigen gene cluster contains 18 genes, spanning about 19 kb of chromosomal DNA (Zhang et al., 1997). Nine genes encode enzymes for the biosynthesis of UDP-GalNAc (*gne*), GDP-Man (*manB* and *manC*), GDP-Fuc (*gmd* and *fcl*) and CDP-6d-Gul (*ddhA*, *ddhB*, *wbcA* and *wbcB*). Of the remaining nine genes five, *wbcC*, *wbcD*, *wbcG*, *wbcH* and *wbcI* code for glycosyltransferases, *wzx* codes for a flippase, *wzy* for an O-antigen polymerase, and *wzz* for a chain-length determi-

nant. One gene, *wbcF*, remains still unassigned (Zhang et al., 1997).

Link 9: *Y. pseudotuberculosis* LPS

No genetic work has been reported on the lipid A and core biosynthesis of *Y. pseudotuberculosis*. The core structure has been reported but still the details of the structure are missing (Ovodov et al., 1992). In silver-stained sodium dodecyl sulfate polyacrylamide gel electrophoresis lipopolysaccharide (SDS-PAGE LPS) of most *Y. pseudotuberculosis* serotypes shows the ladder-like staining pattern as an indication of heteropolymeric O-antigen. However, detection of the ladder of a few serotypes, e.g., O:1b, is very difficult by silver staining. This is due to absence of vicinal hydroxyl-groups in the chemical structure of the O-unit (a requirement for silver staining) and/or expression of very low amounts of the O-antigen by the strain.

Y. pseudotuberculosis O-ANTIGEN

The O-antigen structures of a number of *Y. pseudotuberculosis* serotypes are known (Table 31).

The chromosomal location of the O-antigen gene cluster in *Y. pseudotuberculosis* and also of the cryptic O-antigen gene cluster in *Y. pestis* is between the *hemH* and *gsk* genes (Skurnik et al., 2000). On the basis of sequencing, gene-specific PCR analysis, and hybridization studies, it has been established that all except serotypes O:7, O:9 and O:10 carry the DDH (3,6-dideoxyhexose) biosynthesis genes, named "*ddhDABC*," or their homologues in the beginning of their gene clusters, downstream of the *hemH* gene and the JUMPstart sequence (a 39-bp element common to several polysaccharide gene clusters). The *ddh*

Fig. 43. *Y. enterocolitica* O:8 lipopolysaccharide (LPS). At left, silver stained deoxycholate polyacrylamide gel electrophoresis (DOC-PAGE) analysis of *Y. enterocolitica* O:8 LPS. At right, schematic structure of LPS. Different populations of molecules are indicated.

Fig. 44. O-antigen. Chemical structure of the repeat unit pentasaccharide of *Y. enterocolitica* O:8 heteropolymeric O-antigen.

genes are very similar to those of *Salmonella* (Kessler et al., 1993; Hobbs and Reeves, 1995). DDH reaches a biosynthetic intermediate with the help of the *ddhDABC* block encoded enzymes, and completion of the specific DDH in each serotype requires one or two additional genes that determine the serotype specificity, e.g., *abe* in serotypes O:2a, O:2b, and O:2c; *prt* and *tyv* in serotypes O:4a and O:4b; *prt* in serotypes O:1a and O:1b, and *ascEF* in serotype O:5a; *ascEF* genes are not present in *Salmonella* and are therefore *Y. pseudotuberculosis* O:5a specific (Thorson and Liu, 1993a; Thorson et al., 1993b; Thorson et al., 1993c; Thorson et al., 1994).

In addition to the DDH pathway genes, the O-antigen clusters contain the genes coding for the biosynthetic enzymes of the other sugar components, the respective glycosyltransferases, and the translocation and polymerization proteins Wzx, Wzy and Wzz. Interestingly, on the basis of PCR analysis, all serotypes appear to use a highly identical Wzz protein for chain length determination (Skurnik et al., 2000).

Comparative analysis of a number of *Y. pseudotuberculosis* O-antigen gene clusters just downstream of the *ddh* genes revealed footprints of homologous recombination events and relics of insertion sequence IS630 also observed in *Shigella sonnei*, relating to the evolution of the clusters (Hobbs and Reeves, 1995). Another characteristic feature of the O-antigenic clusters of *Y. pseudotuberculosis* is the presence of numerous intergenic 6–8 nucleotide repeats (Skurnik et al., 2000).

CDP-DDH biosynthesis.

DDHs are formed via a complex biosynthetic pathway beginning with CDP-D-hexoses. Biosynthesis of CDP-Asc (ascarylose), one of the naturally occurring DDH, consists of five enzymatic steps, with CDP-6-deoxy-D-3,4-glucose reductase (E3), a homogeneous enzyme composed of a single polypeptide with a molecular weight of 39,000, participating as the key enzyme in this catalysis (Lo et al., 1994). The corresponding gene (*ascD=ddhD*) is located in the ascarylose biosynthetic cluster. E3 is an NADH (hydrogenated [reduced] nicotinamide-adenine dinucleotide)-dependent enzyme that catalyzes the key reduction of the C-3 deoxygenation step during the formation of CDP-Asc. One FAD (flavine-adenine dinucleotide) and one plant ferredoxin type iron-sulfur center were found to be associated with each molecule of E3 (Miller et al., 1993). E3 employs a short electron-transport chain composed of both FAD and the iron-sulfur center to shuttle electrons from NADH to its acceptor. Cys-75 and Cys-296 may be important for electron transfer between NADH, FAD, and the iron-sulfur center (Ploux et al., 1995).
